CHAPTER 42

Chronic Kidney Disease

Mary K. Stamatakis

Drugs can adversely affect kidney structure and function, leading to acute or chronic nephrotoxicity. Although acute kidney injury (AKI) is commonly recognized as a consequence of drug therapy, drugs have also been associated with chronic kidney disease (CKD), which is defined as an abnormality of kidney structure or function of at least 3 months' duration with implications for health.[1] Criteria for CKD are a glomerular filtration rate (GFR) of <60 mL/min/1.73 m^2 and/or the presence of markers of kidney damage, such as albuminuria or electrolyte abnormalities due to tubular disorders. The term *end-stage renal disease* (ESRD) is typically used to describe the final stage of CKD characterized by a GFR of <15 mL/min/1.73 m^2 requiring renal replacement therapy (e.g., dialysis, kidney transplantation).[1] This chapter summarizes the pathophysiology and treatment of drug-induced CKD.

CAUSATIVE AGENTS

A variety of drugs have been associated with CKD (**Table 42-1**).[2-54] Drugs frequently reported to cause CKD include tacrolimus, cyclosporine, lithium, and combination analgesics (containing at least two antipyretic analgesics, often with the addition of caffeine and/or codeine). CKD is also reported in association with Chinese herbal supplements containing aristolochic acid. Many of the drugs implicated in causing CKD also cause other types of renal diseases. For example, cyclosporine and tacrolimus cause a common dose-related, hemodynamically mediated AKI.[16] Nonsteroidal anti-inflammatory drugs (NSAIDs) can cause hemodynamically mediated AKI as well as acute interstitial nephritis.[55] In addition, drug-induced AKI, such as that associated with aminoglycosides, amphotericin B, and contrast dye, can progress to CKD in some patients.

PROTON PUMP INHIBITORS

Recently, proton pump inhibitors (PPIs), such as omeprazole, esomeprazole, and pantoprazole, were linked to CKD in a population-based observational study of more than 10,000 patients.[47] After 13.9 years of study, researchers found a 50% higher risk of CKD in patients who self-reported use of PPIs. The risk was similar when adjusted for patient variables such as obesity, diabetes, and hypertension. No association was found with self-reported use of H_2 receptor antagonists and CKD. The data were replicated in a cohort of patients receiving care in the Geisinger Health System of Pennsylvania.[47] Although these results do not prove causality, they do raise concern because PPIs are commonly prescribed or self-administered, often with no clear indication. A recent meta-analysis of five studies demonstrated a 1.3-fold increased risk of CKD in patients treated with PPIs.[56] Prospective studies are needed to determine causality as well as understand the potential mechanism of kidney injury and risk factors.

Table 42-1 Agents Implicated in Drug-Induced Chronic Kidney Disease

Drug	Incidence	Level of Evidence[a]
Adefovir[48,49,52]	1–12%[b]	B
Aristolochic acid (Chinese herbs)[2-6]	NK	C
Antipyretic analgesics[7-10,c]	0.8–9%	B
Cidofovir[15]	NK	C
Cisplatin[11,13,35]	10–80%	B
Cyclosporine[16-29]	NK[d,e]	A
Entecavir[53]	<1%	C

Gold salts[30,31]	1–5%[e]	B
Ifosfamide[11,13,32-35]	20–60%	B
Lithium[36-43]	0.2–21%	B
Nitrosoureas (streptozocin, carmustine, lomustine)[14]	10%	C
D-penicillamine[44]	NK	C
Propylthiouracil[45]	NK	C
Proton pump inhibitors[47] (omeprazole, esomeprazole, pantoprazole, rabeprazole, lansoprazole, dexlansoprazole)	NK	B
Tacrolimus[16,18,26,46]	NK[d]	A
Tenofovir[53]	<1%	C

NK = not known, information in the literature is conflicting, or information varies substantially based on indication or dose.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] 10 mg QD dose, rates of 13–50% at higher doses.

[c] Chronic consumption of a combination of at least two antipyretic analgesics, and usually caffeine or codeine or both.

[d] Incidence varies widely based on dose and indication. Average serum creatinine concentration is elevated, glomerular filtration rate is decreased, or both in studies evaluating the long-term safety of calcineurin inhibitors.

[e] In one study, CKD developed in 18% of liver transplant recipients.

ANTIVIRAL AGENTS

Adefovir dipivoxil is a nucleotide analog reverse transcriptase inhibitor indicated for the treatment of chronic hepatitis B (CHB). Adefovir was initially used to treat human immunodeficiency virus (HIV); however, nephrotoxicity was a rate-limiting side effect at the high doses necessary for HIV treatment.[50] The incidence of nephrotoxicity is low at currently recommended doses of 10 mg/day in CHB; however, routine monitoring of serum creatinine is recommended when treatment duration is >1 year as the likelihood of CKD increases with duration of therapy. Every 3-month monitoring is recommended in patients at risk of CKD, including the elderly and those with pre-existing renal disease, diabetes, or hypertension.[51] Entecavir and tenofovir are first-line nucleotide inhibitors used preferentially over adefovir in CHB. Kidney manifestations with entecavir and tenofovir are infrequent, with AKI and hypophosphatemia most frequently observed with tenofovir.[53] The American Association for the Study of Liver Diseases 2016 treatment guidelines of CHB recommend yearly monitoring of serum creatinine in patients treated with entecavir and tenofovir. More frequent monitoring is warranted in patients with pre-existing kidney disease or at risk for its development.[53]

Tenofovir is also administered to patients with HIV as part of a multidrug combination, typically as the tenofovir disoproxil prodrug. AKI and Fanconi syndrome are the most frequently reported kidney manifestations, but CKD may also occur.[54] Tenofovir alafenamide is a new prodrug of tenofovir that maintains antiviral efficacy with smaller doses and has the potential for reduced kidney and bone toxicity. Whether this prodrug will result in less CKD remains to be determined. Other antiviral drugs, such as acyclovir and indinavir, primarily result in AKI, which may rarely progress to ESRD.

This chapter focuses primarily on tacrolimus, cyclosporine, lithium, combination analgesics, and Chinese herbs, the agents most commonly associated with drug-induced CKD.

EPIDEMIOLOGY

TACROLIMUS/CYCLOSPORINE

Tacrolimus and cyclosporine are calcineurin inhibitors that are administered in combination with other immunosuppressive medications to prevent rejection in solid organ transplantation and for prevention and treatment of graft-versus-host disease. These drugs may also be used for the management of autoimmune disorders such as psoriasis, rheumatoid arthritis, ulcerative colitis, Crohn disease, and atopic dermatitis. Tacrolimus and cyclosporine cause both AKI and CKD. Tacrolimus- or cyclosporine-induced AKI typically occurs within 6–12 months after the organ transplantation and is often reversible with dose reduction, whereas drug-induced CKD is progressive, often occurring after 6–12 months of treatment, and may culminate in chronic allograft loss.[16] Tacrolimus and cyclosporine contribute to chronic renal allograft nephropathy to a similar degree and have similar risk factors and clinical presentations. In one early study, CKD (defined as a serum creatinine concentration >2.5 mg/dL) occurred in 18% of liver transplant patients receiving cyclosporine or tacrolimus within 13 years after transplantation; half of those patients experienced progression to ESRD.[26] In heart transplant recipients, the incidence of renal insufficiency, defined as a GFR <60 mL/min/1.73 m^2, increased from 28.8% at baseline to 59.6% at 36 months post-transplantation.[58] In patients receiving cyclosporine for treatment of psoriasis, creatinine clearance declined at a rate of 3.1 mL/min/yr and was associated with interstitial fibrosis and tubular atrophy.[59]

The incidence of drug-induced nephrotoxicity is more difficult to determine in patients who undergo kidney transplantation because chronic rejection, recurring renal disease, and drug-induced nephrotoxicity all can play a role in progressive loss of kidney function. In an early retrospective study of more than 1,600 kidney transplant patients receiving cyclosporine, the average serum creatinine concentration 3 years after transplantation was 1.9 mg/dL.[60] More recent studies have evaluated the incidence of calcineurin inhibitor nephrotoxicity at lower doses. More than 1,600 kidney transplant recipients treated with low-dose tacrolimus in combination with daclizumab induction, mycophenolate, and corticosteroids had a GFR of 65.4 mL/min 12 months post-transplantation, a value which was higher than with patients receiving regimens of standard dose cyclosporine, low-dose cyclosporine, or a calcineurin-free regimen (56–59 mL/min).[28]

Despite numerous studies that have evaluated the chronic nephrotoxicity of these medications, there is a growing body of evidence to support a variety of causes of CKD in the kidney transplant population, with only one component being exposure to calcineurin inhibitors. Results from the Long-term Deterioration of Kidney Allograft Function study of patients with late graft dysfunction and kidney biopsy data showed evidence of antibody-mediated kidney injury in 57% of patients with new-onset late kidney allograft dysfunction.[61] In a study evaluating the causes of kidney allograft loss in more than 1,300 kidney transplant patients, calcineurin inhibitor toxicity alone caused 0.6% of grafts lost, although the authors speculate that the drugs may have contributed to the development or progression of fibrosis and atrophy in about 30% of the grafts lost.[62] Thus, the role of calcineurin inhibitors in overall chronic kidney allograft damage required further study.

LITHIUM

Several renal complications are reported as a consequence of chronic lithium therapy. Well-known manifestations include polyuria, polydipsia, and nephrogenic diabetes insipidus (defined as an inability to concentrate the urine despite normal or increased concentrations of the antidiuretic hormone arginine vasopressin).[42,63] A causal relationship between lithium therapy and CKD has not been conclusively established. Numerous retrospective and cross-sectional studies have described an association between lithium therapy and impaired kidney function, particularly in patients receiving long-term (e.g., 10–20 years) therapy. However, significant variability is reported in the literature, with an incidence ranging from <1% to as high as 21%, and with progression to ESRD occurring rarely.[36-43] Other studies have found no association between lithium intake and reduction in GFR.[64-66] Poor quality of published data, small sample sizes, and exclusion of patients with a history of lithium intoxication limit extrapolation of the results. A meta-analysis of studies published from the 1960s to the present involving patients with mood disorders treated with lithium found only a small risk of renal failure secondary to lithium treatment (overall reduction in GFR of 6.2 mL/min).[65] Other factors such as age, concomitant medications, and occurrence of lithium intoxication may play a role. Thus, the incidence of lithium-induced CKD is not clear. The prevailing consensus is that lithium rarely causes CKD, and its occurrence appears to be related primarily to the duration of administration and cumulative dose.[42]

ANALGESICS

Analgesic nephropathy is defined as CKD resulting from long-term intake (more than 1 year) of two or more antipyretic analgesics, often in combination with substances with potential dependence (e.g., caffeine, codeine).[69] It is estimated that analgesic nephropathy is the cause of kidney failure in <1% of cases in the United States, but it may account for 3–9% of all cases of kidney failure in Europe and Australia, where combination analgesic products have been available without a prescription for longer than in the United States.[7] Analgesics reported to cause CKD include acetaminophen, aspirin, NSAIDs, pyrazolones, and phenacetin.[70] An association between analgesic use and renal failure was first identified in patients consuming phenacetin-containing analgesics.[9,71,72] As a result, phenacetin use has been restricted around the world, and it was removed from the U.S. market in 1983.[73,74] Although these restrictions were followed by a decrease in the incidence of kidney failure secondary to analgesic nephropathy, the overall incidence of drug-induced CKD increased in some regions possibly due to other combinations of analgesics, including those containing acetaminophen.[73]

Acetaminophen is a metabolite of phenacetin, and it has been speculated that acetaminophen could similarly induce CKD, particularly when consumed as part of analgesic combinations. Heavy consumption of acetaminophen has been associated with a dose-dependent increased risk of kidney failure in some studies, although it is not entirely clear in these reports whether patients consumed single-entity or combination products.[9,10,75] In addition, other studies did not find a decrease in GFR following normal or high-dose acetaminophen therapy.[75-77]

The Nurses' Health Study evaluated self-reported lifetime use of acetaminophen, aspirin, and NSAIDs and change in GFR over an 11-year period (1989–2000) in 1,697 women.[74] Acetaminophen, but not aspirin or NSAIDs, was associated with an increased risk of kidney failure and a 30% reduction in GFR. However, other studies have not found a correlation between acetaminophen consumption and kidney failure, particularly at lower acetaminophen doses. The National Kidney Foundation expert panel on analgesic nephropathy issued a consensus statement that the habitual use of combination antipyretic analgesics is associated with an increased prevalence of CKD, whereas the use of single-entity products (aspirin, acetaminophen, NSAIDs) appears to carry a lower risk for analgesic nephropathy.[69] Further, the panel's statement indicates that acetaminophen remains the non-narcotic analgesic of choice in patients with kidney failure, although habitual consumption is not recommended.[69] In summary, there is little convincing evidence that acetaminophen causes analgesic nephropathy when used alone and at recommended doses.

Conflicting data also exist regarding NSAID use and worsening CKD. High-dose NSAIDs may accelerate progression of CKD, although chronic consumption of regular-dose NSAIDs does not appear to have the same effect. In addition, NSAIDs may worsen hypertension, lead to hyperkalemia, and may cause a prostaglandin-mediated decrease in renal blood flow resulting in AKI. Therefore, routine monitoring of kidney function is required with use of NSAIDs, particularly in individuals with reduced GFR and in the elderly.

DIETARY SUPPLEMENTS CONTAINING ARISTOLOCHIC ACID

Nephropathy associated with Chinese herbs was first identified in the early 1990s in Belgium after kidney failure developed in nine patients from the same weight loss clinic in association with weight reduction regimens containing Chinese herbs.[6] It was subsequently confirmed that weight reduction regimens from this clinic inadvertently contained plant material from species of *Aristolochia*.[3] *Aristolochia* contains aristolochic acids I and II, which are known nephrotoxins.[78] One cross-sectional survey in adult Chinese participants found an association between aristolochic acid intake and GFR <60 mL/min/1.73 m^2 and albuminuria.[79] Originally termed *Chinese herb nephropathy*, the condition has been renamed *aristolochic acid nephropathy* (AAN) because exposure has occurred secondary to food contamination and in the manufacturing of dietary supplements.[80] Although the incidence is not known, nephropathy associated with Chinese herbs has been reported worldwide. Urinary tract cancer has also been associated with aristolochic acid, which resulted in its classification as a carcinogen by the International Agency for Research on Cancer. Since the early 1990s, many countries have banned the use of *Aristolochia* species. In 2001, the U.S. Food and Drug Administration (FDA) issued an alert indicating that dietary supplements are unsafe if they contain (or there is even a suspicion that they contain) aristolochic acids.[81] Manufacturers have been warned to remove aristolochic acid from their products, and any products containing aristolochic acid are considered unsafe and adulterated.[82] However, even with these warnings, cases of AAN continue to be reported around the world, and the product may be available online.[78]

MECHANISMS

TACROLIMUS/CYCLOSPORINE

CKD induced by tacrolimus and cyclosporine typically presents as chronic tubulointerstitial nephritis, characterized on renal biopsy as interstitial fibrosis appearing in a "striped" pattern, widespread tubular atrophy, and to a lesser extent, glomerulosclerosis. Renal arteriolar hyalinosis is a primary manifestation thought to be indicative of cyclosporine- or tacrolimus-induced CKD.[17] Glomerular changes may be absent or may occur only in more advanced stages of CKD. Direct vascular toxicity and direct tubular toxicity have also been suggested as mechanisms for chronic kidney injury.[17] Direct vascular toxicity of endothelial cells and release of vasoactive substances, cytokines, and growth factors lead to tubulointerstitial fibrosis and glomerulosclerosis. In addition, direct tubular toxicity may occur after long-term exposure to calcineurin inhibitors because of the induction of apoptosis and inhibition of P-glycoprotein, thus allowing intracellular calcineurin inhibitor accumulation.[84] Biopsies from patients who received kidney-pancreas transplants demonstrated severe chronic allograft nephropathy in 58.4% of patients and glomerulosclerosis in 37.3%.[20] Mechanisms of CKD are described in **Table 42-2**.

LITHIUM

Lithium-induced CKD presents as chronic tubulointerstitial nephritis, characterized on renal biopsy as interstitial fibrosis and inflammation, widespread tubular atrophy, and glomerulosclerosis. Distal tubular dilation, glycogen deposition, and microcyst formation have been reported in lithium-treated patients with CKD.[83,85,86] The mechanism of lithium-induced CKD is not known but has been speculated to be decreased intracellular formation of cyclic adenosine monophosphate or inhibition of water transport in the cortical collecting duct.[67]

Table 42-2 Mechanisms of Drug-Induced Chronic Kidney Disease

Drug	Mechanism
Adefovir/cidofovir/entecavir/tenofovir[15,49-50]	Proximal renal tubular injury, tubular atrophy
Aristolochic acid (Chinese herbs)[4,5]	Interstitial fibrosis, tubular atrophy
Antipyretic analgesics[8,a]	Papillary necrosis, interstitial nephritis
Cisplatin[12,14]	Interstitial fibrosis, tubular atrophy
Cyclosporine[17,84]	Interstitial fibrosis, tubular atrophy, afferent arteriolopathy
Gold salts[30,31]	Proteinuria, membranous glomerulonephritis, minimal-change disease, immune complex mesangial glomerulonephritis

Ifosfamide[13-14]	Interstitial fibrosis, tubular atrophy
Lithium[83,85-86]	interstitial fibrosis, tubular atrophy, tubular cysts
Nitrosoureas (streptozocin, carmustine, lomustine)[14]	Glomerulosclerosis, interstitial fibrosis, tubular atrophy
D-penicillamine[44]	Proteinuria, membranous nephropathy, immune complex mesangial glomerulonephritis, rapidly progressive crescentic glomerulonephritis
Propylthiouracil[45]	Glomerulonephritis, tubulointerstitial nephritis
Tacrolimus[17,84]	Interstitial fibrosis, tubular atrophy, afferent arteriolopathy

[a] Chronic consumption of a combination of at least two antipyretic analgesics, and usually caffeine or codeine or both.

ANALGESICS

Papillary necrosis associated with calcification is a hallmark feature of analgesic nephropathy and often precedes the development of cortical changes.[8] A potential mechanism for the toxicity of combination analgesics has been suggested.[8] Acetaminophen and phenacetin are primarily removed from the body by renal excretion of glucuronides. However, acetaminophen is also oxidized to *N*-acetyl-benzoquinoneimine, a highly reactive intermediate, which accumulates in the papillae of the kidney. Reduced glutathione can quickly react with and decrease free radical toxicity; however, concomitant ingestion of salicylates depletes renal medullary glutathione, thus enabling the reactive metabolites to cause papillary necrosis. In addition, decreased synthesis of vasodilatory prostaglandins by NSAIDs and salicylates can cause renal ischemia.[8]

DIETARY SUPPLEMENTS CONTAINING ARISTOLOCHIC ACID

Pathologic features associated with AAN include extensive interstitial fibrosis and tubular atrophy, with the most significant lesions in the superficial cortex.[4] Glomerulosclerosis is more limited and is often secondary to tubular and interstitial damage. Thickening of Bowman's capsule and swelling of interlobar and afferent arteriole walls may also be present.[4] Because the cortex is most severely damaged, it has been speculated that direct proximal-tubule epithelial cell damage is the most likely mechanism.[5] It has also been suggested that the primary lesion occurs in small arterial walls, leading to ischemia and interstitial fibrosis, or that interstitial fibroblasts are stimulated directly.[5]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Patients with drug-induced CKD typically present with nonspecific symptoms attributed to kidney failure. Table 42-3 lists signs and symptoms commonly associated with CKD, including drug-induced causes. In addition to drugs, a variety of medical conditions can lead to CKD. Table 42-4 lists conditions to be considered in the differential diagnosis of drug-induced CKD.

Table 42-3 Signs and Symptoms Associated with Drug-Induced Chronic Kidney Disease

Water and sodium imbalance

- Elevated blood pressure
- Nocturia
- Peripheral edema
- Pulmonary edema
- Weight gain

Hematologic

- Anemia
- Bleeding
- Dizziness
- Fatigue
- Headache
- Shortness of breath

Hyperphosphatemia

- Persistent itching

Urinary

- Decreased urine output
- Blood in urine
- Protein in urine

Hyperkalemia

- Palpitations or irregular heartbeat
- Numbness or tingling

Cardiovascular

- Chest pain
- Dizziness
- Edema
- Fatigue
- Headache
- Hypertension

- Nervousness

Neurologic

- Fatigue
- Insomnia and sleep disturbances
- Malaise
- Paresthesias
- Restless legs
- Seizures
- Weakness

Gastrointestinal

- Diarrhea or constipation
- Nausea, vomiting, anorexia
- Unpleasant taste

Metabolic/endocrine

- Bone fractures
- Bone pain
- Glucose intolerance
- Gout
- Growth retardation
- Sexual dysfunction

Nutritional

- Anorexia
- Decreased muscle mass
- Weight loss
- Proteinuria (gold salts, D-penicillamine, nonsteroidal anti-inflammatory agents)

Psychological

- Anxiety
- Depression
- Psychosis

Dermatologic

- Pigmentation
- Pruritus

Table 42-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Chronic Kidney Disease

- Chronic rejection of a transplanted kidney
- Cystic kidney disease
- Diabetic nephropathy
- Glomerulonephritis
- Hereditary (e.g., Alport disease)
- Hypertensive nephrosclerosis
- Obstructive uropathy

- Pyelonephritis
- Renal vascular disease

TACROLIMUS/CYCLOSPORINE

CKD induced by tacrolimus or cyclosporine occurs insidiously, usually beginning after at least 6–12 months of therapy. Patients have an increase in serum creatinine and blood urea nitrogen (BUN) concentrations and often present with hypertension. Differentiating chronic organ rejection from drug-induced nephrotoxicity is difficult, especially in kidney transplant recipients.[16] Kidney biopsy findings associated with chronic cyclosporine or tacrolimus nephrotoxicity include nodular arterial hyalinosis, tubular atrophy, glomerulosclerosis, and tubulointerstitial fibrosis in a “striped” pattern.[57,87-89] Manifestations of cyclosporine- or tacrolimus-associated CKD are similar to those of other causes of CKD (e.g., fluid overload, anemia, electrolyte abnormalities). Recent evidence suggests that calcineurin inhibitor use may not be a major factor in late graft loss, and that immune injury from donor antibodies may play a prominent role.[90]

LITHIUM

Patients with lithium-induced CKD present with an insidious increase in serum creatinine and BUN concentrations, often after decades or more of treatment.[91] Patients may present rarely with hypertension and proteinuria. In most reported cases of lithium-induced CKD, reduction in renal function was mild (creatinine clearance >50 mL/min). Progression of CKD to ESRD is uncommon.[43]

ANALGESICS

Patients with analgesic-induced nephropathy develop an insidious increase in BUN and serum creatinine concentrations.[92] Symptoms of renal failure secondary to analgesic nephropathy are nonspecific. Patients may rarely report renal colic and hematuria secondary to excreting necrotic papilla in the urine.[8] A careful medication history is needed to determine a pattern of analgesic use that lists lifetime usage of prescription and nonprescription medications, including those that are no longer commercially available. Daily consumption of analgesic combinations for more than 1 year is highly indicative of abuse.[69] In suspected cases, a computed tomography (CT) scan without contrast medium is indicated. In patients with analgesic-induced nephropathy, the CT scan reveals decreased bilateral renal mass in addition to bumpy contours of the kidney, papillary calcifications, or both.[70]

DIETARY SUPPLEMENTS CONTAINING ARISTOLOCHIC ACID

Patients with AAN typically present with nonspecific findings attributed to CKD, although anemia may be more pronounced than expected based on the stage of CKD.[92] In addition, mild proteinuria and glycosuria may be present.[93] An accurate medication history to confirm ingestion of Chinese herbs is critical to the diagnosis. Aristolochic acid was found not only in dietary supplements but also in supplements for arthritis, pain, and hepatitis.[2] Kidney size is decreased, and diagnosis may be confirmed with a kidney biopsy, which reveals extensive interstitial fibrosis.[92] In addition, urothelial lesions or urothelial transitional cell carcinoma may also be present.[94] Progression to ESRD occurs rapidly.[78]

RISK FACTORS

Although risk factors for CKD induced by calcineurin inhibitors and analgesics have been identified (**Table 42-5**), risk factors for CKD caused by other drugs are not well defined.

Table 42-5 Risk Factors for Drug-Induced Chronic Kidney Disease

Cyclosporine/tacrolimus

- Age >50 years
- Diminished pretreatment renal function
- Higher cumulative dose
- Increased duration of exposure
- Number of episodes of acute renal failure secondary to cyclosporine or tacrolimus
- Number of rejection episodes
- Poor kidney function in the first 3–12 months after surgery
- Postoperative acute renal failure

Lithium (risk factors not well established, but may include the following)

- Concurrent treatment with other psychotropic drugs
- Episodes of acute lithium intoxication
- Higher cumulative doses
- Longer durations of exposure
- Occurrence of nephrogenic diabetes insipidus
- Serum creatinine concentration ≥2.5 mg/dL at diagnosis

Antipyretic analgesics (long-term use, usually in combination with caffeine or codeine or both)

- ≥1 g daily for ≥1 year
- Cumulative doses of 1–3 kg

Aristolochic acid

- Risk factors not established; dose and duration of therapy have been speculated to be risk factors

TACROLIMUS/CYCLOSPORINE

Some risk factors for developing tacrolimus- or cyclosporine-induced CKD have been more clearly elucidated than others. Potential risk factors include increased length of exposure (minimum duration 6–12 months), higher cumulative dose, poor kidney function during the first 3–12 months after transplantation, episodes of cyclosporine- or tacrolimus-induced AKI, at least one acute rejection episode, diminished pretreatment renal function (GFR <70 mL/min/1.73 m^2), postoperative AKI, and age >50 years.[16,17,23,95-99] Diabetes and hypertension may have a role.[23] There is no consistent correlation between trough cyclosporine or tacrolimus concentrations and the development of chronic nephropathy.[100]

LITHIUM

The most consistent risk factor for lithium-induced CKD is duration of therapy.[43] One study found a decrease in GFR of 0.64 mL/min/yr of lithium treatment.[101] Other risk factors have not been clearly identified. It has been speculated that episodes of acute lithium intoxication and nephrogenic diabetes insipidus may contribute to development of CKD.[37] Long-term concurrent treatment with other psychotropic drugs is another potential risk factor.[37] Daily lithium dose and serum lithium concentrations do not appear to be risk factors, although once-daily dosing has been speculated to pose less risk than multiple-daily dosing due to tubular regeneration with once-daily administration.[102] It is unknown whether pre-existing CKD is a risk factor for renal toxicity. Increased individual sensitivity to lithium has not been demonstrated, but lithium sensitivity could explain why CKD develops in some patients but not others.

ANALGESICS

The primary risk factor for analgesic nephropathy is long-term consumption of antipyretic analgesics. Consumption of these drugs in doses of ≥1 g daily for 1 year or more are at increased risk, as are individuals consuming cumulative amounts of 1 to 3 kg or more.[72,103] It has been suggested that analgesics containing caffeine may increase the risk of nephropathy, but the role of caffeine in analgesic-induced CKD has not been clearly elucidated.[104] Caffeine may inhibit prostaglandin synthesis via suppression of cyclooxygenase-2, decrease medullary oxygen supply, or promote analgesic dependence.[104] There is limited evidence that long-term consumption of acetaminophen alone leads to analgesic nephropathy, although its role as a cause of this drug-induced disease cannot be excluded completely.

DIETARY SUPPLEMENTS CONTAINING ARISTOLOCHIC ACID

Risk factors for AAN have not been well established. It has been speculated that dose, duration of therapy, and concurrent ingestion of dexfenfluramine, phentermine, or both may increase the risk.[92] In addition, most cases of AAN have occurred in women. However, women are more likely to consume weight-loss products than men and may therefore have increased risk of exposure to Chinese herbs. Whether female sex is a risk factor for nephropathy induced by Chinese herbs is not known.

MORBIDITY AND MORTALITY

TACROLIMUS/CYCLOSPORINE

Chronic allograft nephropathy is a term that was used historically to characterize the syndrome that encompasses both chronic kidney rejection and calcineurin toxicity in kidney transplant recipients.[90] However, morbidity and mortality risk associated with the drugs needs to be further elucidated given the uncertainty about whether the kidney injury is solely attributable to calcineurin use as recent evidence suggests that calcineurin inhibitor nephrotoxicity may not be the major factor in late graft failure and that antibody-mediated rejection may predominate.[90]

Chronic allograft nephropathy resulting in graft loss has been reported to occur in approximately 10–40% of heart transplant recipients.[58] In lung transplant recipients, kidney failure developed in 15% of tacrolimus-treated patients at 1 year.[46] In a study of heart transplant recipients receiving cyclosporine, there was a 12% probability of developing stage 5 CKD at 10 years postoperative.[27]

LITHIUM

Lithium-induced CKD results in mild reduction in renal function. Studies have reported a yearly decrease in GFR ranging from 0.64 mL/min to 2.29 mL/min.[42,101] In a study of 61 patients receiving lithium for an average of 15.6 years, estimated GFR was 66.1 mL/min compared to 75 mL/min in the control group.[105] Rarely does lithium-induced CKD progress to ESRD and necessitate dialysis.

ANALGESICS

Progression to kidney failure is likely if chronic analgesic consumption continues. Discontinuation of analgesics may slow progression, but renal function is not likely to improve.

DIETARY SUPPLEMENTS CONTAINING ARISTOLOCHIC ACID

Progression to kidney failure occurs at a very rapid rate, typically within 1–7 years.[80] There is some evidence that high cumulative exposure causes faster progression to ESRD.[80] Progression of CKD may continue even after discontinuation of the herb-containing supplement.[92]

PREVENTION

Prevention of drug-induced CKD includes routine monitoring of kidney function and evaluation of patients for signs and symptoms associated with CKD (**Table 42-6**).

Table 42-6 Approaches to Help Prevent Drug-Induced Chronic Kidney Disease

Cyclosporine

- Avoid concurrent nephrotoxic medications
- Minimize dose and duration of use
- Assess renal function up to twice weekly in new transplant recipients; with decreasing frequency in individuals with stable kidney function (monthly to yearly evaluation)

Lithium

- Avoid acute lithium intoxication
- Avoid elevated serum lithium concentrations
- Consider withdrawal of lithium to minimize length and total drug exposure in patients with decreased kidney function suspected to be due to lithium (based on risk–benefit assessment determined on an individual basis)
- Assess renal function every 6–12 months

Antipyretic analgesics

- Completely preventable by avoidance
- Institute interventions to curb analgesic abuse

Chinese herbs (aristolochic acid)

- Completely preventable by avoidance
- Glucocorticoids may delay progression to ESRD[3]

ESRD = end-stage renal disease.

TACROLIMUS/CYCLOSPORINE

Whether it is possible to prevent development of chronic nephrotoxicity from calcineurin inhibitors is a subject of much debate. Increased duration of exposure and increased cumulative drug exposure have been postulated to cause chronic renal damage, but an association between blood cyclosporine concentrations and CKD has not been established.[17,96] Thus, routine monitoring of trough blood cyclosporine concentrations does not aid in preventing CKD as it does in AKI. Eliminating or reducing patient exposure to calcineurin inhibitors has been one strategy to prevent development of CKD. Although some studies found lower mean serum creatinine concentrations with regimens not containing calcineurin inhibitors compared to regimens containing the combination of mycophenolate and steroids with calcineurin inhibitors, other studies found decreased allograft survival when tacrolimus and cyclosporine are excluded.[106,107] Total avoidance of calcineurin inhibitors result in reduced graft survival in liver transplant recipients.[21] One study using data from the Scientific Registry of Renal Transplant Recipients demonstrated decreased allograft survival when tacrolimus and cyclosporine are excluded (64% allograft survival) compared to regimens containing cyclosporine or tacrolimus (78% allograft survival).[107] Other protocols that discontinued calcineurin inhibitors in patients who had initially received them demonstrated mixed results.[100]

The National Kidney Foundation and the Kidney Disease Outcomes Quality Initiative Clinical Practice Guidelines recommend initial therapy with tacrolimus compared to a calcineurin-free regimen in kidney transplantation. In cases where chronic allograft injury develops, dose reduction followed by calcineurin withdrawal can be considered.[29,108]

LITHIUM

Elevated serum lithium concentrations may predispose patients to lithium-related adverse effects. In addition, some evidence suggests that episodes of acute intoxication or the occurrence of nephrogenic diabetes insipidus can predispose a patient to CKD.[37] Thus, it is recommended to maintain serum lithium concentrations as low as clinically feasible. It is also important to rule out other causes of renal failure (e.g., diabetes, hypertension) and to establish the relative contribution of each risk factor. Whether discontinuation of lithium leads to improvement in the GFR is not clear. Kidney function should be assessed every 2–3 months during the first 6 months of lithium treatment and at least yearly in stable patients; more frequent monitoring is indicated in higher-risk patients (e.g., increased age, occurrence of lithium intoxication).[109]

ANALGESICS

Analgesic nephropathy is one of the few preventable causes of CKD. Because the primary risk factor is long-term consumption of non-narcotic analgesics, identification of analgesic abuse and interventions to curb abuse may prevent progression to ESRD. Discontinuation of analgesics may stabilize kidney function, but kidney function is not likely to return to baseline.[110] More importantly, limiting the sale of combination analgesics can decrease the prevalence of analgesic-induced CKD. The National Kidney Foundation recommends that the "availability of analgesic mixtures as an over-the-counter (OTC) product should cease" and prescription products should bear a warning of the association between kidney disease and the habitual consumption of analgesic mixtures.[69] However, combination OTC analgesic products remain commercially available.

DIETARY SUPPLEMENTS CONTAINING ARISTOLOCHIC ACID

Avoiding the use of *Aristolochia* species prevents AAN. In 2001, the FDA issued an alert stating that dietary supplements are unsafe if they contain (or if there is even a suspicion that they may contain) aristolochic acids.[81] Manufacturers of dietary supplements must ensure the safety of their products with strict manufacturing procedures that ensure that these products do not contain aristolochic acid. Despite this warning, products containing aristolochic acids may still be available over the Internet.[111] In one study, aristolochic acids I and II were found in 20% and 7%, respectively, of 30 herbal products marketed in the United States via the Internet.[112] Practitioners must consider the potential role of dietary supplements when evaluating new patients presenting with kidney disease. The public also needs to be made aware of the potential dangers associated with such herbal products.

MANAGEMENT

Management of drug-induced CKD is largely supportive. General recommendations for managing complications associated with CKD are presented in **Table 42-7**.

TACROLIMUS/CYCLOSPORINE

There is presently no effective treatment for tacrolimus- or cyclosporine-induced chronic nephrotoxicity.[113] Withdrawal of therapy or substitution of alternative immunosuppressive agents (e.g., sirolimus) may slow the rate of loss of renal function or lead to improvements in GFR.[114] However, the benefits of continued therapy in terms of graft survival must be weighed against the risk of drug-induced CKD. Routine monitoring of renal function is required in all patients treated with cyclosporine or tacrolimus.

LITHIUM

Although there are multiple treatment options for lithium-induced polyuria (e.g., thiazides, amiloride, indomethacin), less is known about effective treatment for lithium-induced CKD. Minimizing progression with an angiotensin-converting enzyme inhibitor, normalizing blood pressure, and avoiding other nephrotoxic medications have been suggested.[115] Whether discontinuation of lithium therapy decreases progression of lithium-induced CKD remains controversial. Because rate of progression to CKD is slow, lithium could be tapered slowly while alternative treatment is titrated upward.[68]

Table 42-7 Treatment Options for the Management of Drug-Induced Chronic Kidney Disease

- Discontinue the offending agent (may lead to reversal or halt progression of CKD) and administer less nephrotoxic medication
- Dialysis or kidney transplantation (if progression to end-stage renal disease)
- Treatment of common complications of CKD:
  - Anemia—erythropoietin or darbepoetin; iron
  - Bleeding—red-cell transfusion, DDAVP, conjugated estrogens, erythropoietin
  - Hyperkalemia—dietary potassium restriction, sodium polystyrene sulfonate, intravenous calcium, intravenous insulin and glucose, intravenous sodium bicarbonate
  - Hyperlipidemia—bile acid sequestrants, nicotinic acid, statins, gemfibrozil, clofibrate, probucol
  - Hyperphosphatemia/secondary hyperparathyroidism—dietary phosphorus restriction, phosphate binders, calcium supplements, vitamin D analogs, calcimimetics, parathyroidectomy
  - Hypertension—All classes of antihypertensives can be used; multidrug regimens may be needed; select therapy based on concomitant medical needs
  - Malnutrition—vitamin and nutritional supplements
  - Water and sodium imbalance—sodium restriction, diuretics

CKD = chronic kidney disease, DDAVP = 1-deamino-8-D-arginine vasopressin.

ANALGESICS

Discontinuation of analgesic consumption is a primary treatment goal, as this may prevent progression of CKD.[116] In patients with established nephropathy, complications of CKD should be treated and dialysis initiated as indicated.

DIETARY SUPPLEMENTS CONTAINING ARISTOLOCHIC ACID

There is no specific treatment for AAN. In rare cases, CKD is reversible with discontinuation of treatment.[117] However, in at least 70% of cases, patients progress to stage 5 CKD and require either dialysis or kidney transplantation.[81] One small study found that corticosteroids slowed progression to kidney failure.[118]

INFORMATION FOR PATIENTS

Patients receiving medications such as cyclosporine, tacrolimus, and lithium (Table 42-1) should be instructed that routine blood work for assessment of renal function is essential, because patients remain asymptomatic until creatinine clearance is significantly reduced (<30 mL/min). Patients should be counseled regarding the signs and symptoms associated with CKD (Table 42-3) and should be instructed to seek medical attention if any of these occur.

In addition, patients must recognize that nonprescription medications can cause nephrotoxicity. Acetaminophen remains the non-narcotic analgesic of choice in individuals with CKD. However, patients should be informed that acetaminophen is not intended for long-term consumption and that any long-term use should be undertaken with the supervision of the patient’s healthcare providers. In addition, patients should be educated about the association of kidney injury with long-term consumption of combination analgesics, and chronic use should be strongly discouraged. Patients should be informed that the FDA regulates dietary supplements as foods rather than drugs, and therefore products are not required to undergo the same rigorous clinical testing and quality control as drugs. Caution in using these products is advised. Importantly, patients should be instructed that diet aids containing aristolochic acid can lead to development of CKD and that their use must be immediately discontinued.

CHAPTER 43

Syndrome of Inappropriate Antidiuretic Hormone Secretion and Diabetes Insipidus

Mark A. Malesker and Daniel E. Hilleman

The syndrome of inappropriate antidiuretic hormone secretion (SIADH) and diabetes insipidus (DI) are conditions of altered water balance related to the abnormal secretion and/or action of antidiuretic hormone (ADH), also known as arginine vasopressin (AVP). ADH is produced in the posterior pituitary gland and acts to increase cellular permeability to water in the distal tubule and the collecting duct of the nephron, thus increasing water reabsorption. SIADH causes reabsorption of water in the nephron that is inappropriate for the patient's serum osmolality, and this results in hyponatremia. Conversely, DI causes hypernatremia due to the loss of large amounts of dilute urine. DI can be either central (reduced secretion of ADH) or nephrogenic (reduced sensitivity to ADH in the nephron) in origin.[1-6] There are many causes of SIADH and DI and both can be drug-induced.

SIADH

CAUSATIVE AGENTS

Drugs that have been reported to cause SIADH are listed in **Table 43-1**.[7-252] Antidepressants (in particular the selective serotonin reuptake inhibitors or SSRIs); the serotonin–norepinephrine reuptake inhibitors (SNRIs) venlafaxine and duloxetine; chemotherapy agents including vinca alkaloids, cisplatin, and cyclophosphamide; the anticonvulsants carbamazepine and oxcarbazepine; and the sulfonylureas are the agents most strongly associated with SIADH. Methylenedioxymetham-phetamine (MDMA or “ecstasy”)-induced SIADH has been widely reported in the literature. Other medications that have been implicated in SIADH, but are less well studied, include the angiotensin–converting enzyme inhibitors and amiodarone.

Table 43-1 Agents Implicated in Drug-Induced Syndrome of Inappropriate Antidiuretic Hormone Secretion

Drug	Incidence	Level of Evidence[a]
SSRIs[b]		
Citalopram[7-19]	NK	C
Escitalopram[20-23]	NK	C
Fluoxetine[24-40]	NK	C
Fluvoxamine[41,42]	NK	C

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] The overall incidence of drug-induced SIADH with SSRIs was reported to be as high as 39% in one case-control study.[252]

EPIDEMIOLOGY

The exact incidence of drug-induced SIADH is not known but is likely very low. The incidence is difficult to determine because most studies are small and retrospective. In addition, most studies use hyponatremia rather than urine electrolyte concentrations and osmolality as criteria for diagnosing SIADH. Urine electrolyte concentrations and osmolality are much better indicators of SIADH, although they are rarely reported. Additionally, varying definitions of hyponatremia have been used in case reports and studies and during postmarketing surveillance. Some studies, for example, have used mild hyponatremia (e.g., serum sodium <135 mEq/L) as the sole marker for SIADH. This approach may result in a higher reported incidence of SIADH associated with a given drug, even though relatively small decreases in serum sodium concentrations likely have negligible clinical significance.

Most of the clinical studies of drug-induced SIADH involve antidepressants, in particular the SSRIs, and are primarily retrospective, case-control studies conducted in psychiatric inpatients.[56,114,252,254,256] In one such study, 39% of elderly psychiatric inpatients receiving an SSRI or venlafaxine (a norepinephrine–serotonin reuptake inhibitor) had hyponatremia (defined as serum sodium concentrations <135 mEq/L), as compared with an incidence of 10% in controls.[252] In a retrospective case study, the incidence of symptomatic SIADH due to SSRIs was 12.5%; however, this incidence may be overstated due to the retrospective nature of the trial and because patients were identified through hospital admissions and may not represent an otherwise “healthy” population.[255] No cases of hyponatremia were found in a retrospective review of 246 primarily male patients receiving sertraline, while a prospective trial noted an incidence of 17.2%.[114,256] A prospective study of paroxetine in 75 patients (age 63–90 years) in an ambulatory psychiatric clinic revealed an incidence of hyponatremia (defined as serum sodium concentration <135 mEq/L) of 12%.[56] Venlafaxine has been associated with an even higher risk of hyponatremia in psychiatric inpatients.[252]

Although many case reports have associated antipsychotics with SIADH, a retrospective study of 328 patients being treated for schizophrenia failed to find such a relationship. The authors suggest that schizophrenia itself (or perhaps other factors), and not the drugs used to treat the disease, is the cause of hyponatremia in this patient population.[257]

Carbamazepine is well known to cause SIADH. The reported incidence varies from 4.8% to 40%.[170,258] Oxcarbazepine is a 10-keto analog of carbamazepine that may be associated with a higher incidence of hyponatremia secondary to SIADH.[170,177,259] Hyponatremia (serum sodium concentrations <135 mEq/L) has been estimated to occur in as many as 25% to 29.9% of patients receiving oxcarbazepine.[170,259] In a cross-sectional study of 548 patients, the incidence of hyponatremia (with serum sodium concentrations <128 mEq/L) associated with carbamazepine and oxcarbazepine was 2.8% and 12.4%, respectively.[170] In one study, approximately 40% of patients experienced a reduction in serum sodium concentration when carbamazepine was replaced with oxcarbazepine, although most changes were mild and probably of no clinical significance.[177]

Chlorpropamide has frequently been associated with SIADH, but is no longer widely prescribed in the United States for diabetes management. Two percent of patients receiving chlorpropamide were found to experience hyponatremia with a serum sodium concentration of <130 mEq/L, while 7% experienced hyponatremia with concentrations in the range of 130–134 mEq/L.[183] Hyponatremia or SIADH associated with the newer-generation sulfonylureas has been recognized in postmarketing surveillance.[188-190]

A retrospective review of 1,436 MDMA (ecstasy) intoxication cases in California revealed a 34.5% incidence of hyponatremia (serum sodium concentration <130 mEq/L) among the 188 patients who had serum sodium concentrations reported.[260] This incidence is likely higher than what would be seen in the general population of MDMA users, as patients who presented with significant mental-status changes were probably more likely to have had a serum sodium concentration measured.

MECHANISMS

The precise mechanisms of drug-induced SIADH are not well understood. The disorder occurs as a result of either an increase in central ADH production (as occurs with cyclophosphamide, carbamazepine, vinca alkaloids, antidepressants, and antipsychotics) or an increased sensitivity to ADH at the level of the nephron (as occurs with chlorpropamide, carbamazepine, and cyclophosphamide).[5]

Animal models suggest that 5-hydroxytry-ptophan (HT or serotonin) stimulates ADH release.[261-263] Specifically, 5-HT_{2C}, 5-HTs_4, and 5-HT_7 receptors are implicated in the pathogenesis of drug-induced SIADH.[261] MDMA is known to have serotoninergic activity, and the likely mechanism for MDMA-induced SIADH, therefore, is increased ADH release.[226] A small prospective study of eight healthy volunteers showed that even small doses of MDMA could cause increased secretion of ADH, most likely due to central serotoninergic stimulation.[233] This effect may be attributed to both the parent compound and its metabolites.[264]

A study in patients with epilepsy and healthy volunteers assessed water disposition before and after oxcarbazepine administration. Oxcarbazepine exposure resulted in reductions in serum sodium concentrations and osmolality after water loading in both groups. There was no difference in serum ADH concentrations before or after oxcarbazepine exposure, suggesting that the hyponatremia might be due to increased sensitivity to ADH or even a direct antidiuretic effect rather than inappropriate secretion of ADH.[265] However, because the variation in ADH serum concentrations that may normally occur within a given range of serum osmolality is not known and serum ADH concentrations are not a routine part of the diagnostic workup for SIADH, this study cannot be considered conclusive. More studies will be needed before the exact mechanism(s) of oxcarbazepine-induced SIADH is understood.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

SIADH is associated with a decreased volume of inappropriately highly concentrated urine (e.g., urinary sodium >40 mEq/L and urinary osmolality >100 mOsm/kg water). If fluid intake is not significantly reduced, the increased water reabsorption in the nephron leads to a dilutional hyponatremia. Patients with SIADH present with normal volume status (euvolemia) because the excess water distributes throughout the body’s fluid compartments. Because sodium and its associated anions are the primary contributors to extracellular tonicity, hypotonicity ensues. Symptoms of hyponatremia are related to the degree of serum hypotonicity and the time frame over which hypotonicity occurs. Signs and symptoms of hyponatremia are listed in **Table 43-2**. The most important manifestations of hypotonicity involve the central nervous system, because serum hypotonicity causes water to move into cells, resulting in cerebral cellular swelling. Hyponatremia caused by SIADH is generally not acute, usually developing over >48 hours. As a result, patients may experience only mild symptoms or may be completely asymptomatic. If hyponatremia is acute and serum sodium concentrations are <120 mEq/L, patients can present with symptoms such as headache, nausea, vomiting, muscle weakness, or mental-status changes. Serum sodium concentrations <110 mEq/L can be associated with more severe symptoms, including gait disturbances and potential falls, stupor, coma, seizures, and, rarely, death.[1-3,266]

Table 43-2 Signs and Symptoms Associated with Drug-Induced Syndrome of Inappropriate Antidiuretic Hormone Secretion (Hyponatremia)[1-3,a]

Moderate

- Anorexia
- Headache
- Malaise
- Mental status changes
- Muscle weakness and cramps
- Nausea
- Vomiting

Severe

- Coma
- Gait disturbances
- Seizure
- Stupor

[a] Signs and symptoms associated with hyponatremia due to SIADH are often mild or absent, because hyponatremia often occurs over a long period of time.

Analyses of reported cases of SSRI-associated SIADH reveal that hyponatremia occurs 3–120 days after the initiation of therapy, with a median time to onset of 13–15 days.[267,268] In a prospective study, the mean time from the start of therapy to the onset of hyponatremia was 9.3 days, with a range of 1–14 days.[56] Venlafaxine-induced SIADH may occur within 3–5 days following initiation of drug therapy.[114] Oxcarbazepine-induced SIADH usually develops within the first 3 months of therapy.[176] Hyponatremia has been detected within 3–10 days after exposure to the vinca alkaloids.[67,155,160]

Hyponatremia appears to occur much more quickly in association with MDMA than with other drugs known to cause SIADH. Patients generally present with symptoms within 12–24 hours after drug ingestion. The rapid onset of symptoms is probably partially due to MDMA users often concomitantly ingesting large amounts of nonalcoholic or alcoholic beverages, which compounds the inadequate renal response to water loading caused by the drug. In one published case series, 17 patients with MDMA-induced SIADH and hyponatremia presented with a constellation of symptoms including vomiting, behavioral changes, drowsiness, agitation, and (in 11 of 17 cases), seizures.[227] Another larger review of 553 documented cases of exposure to MDMA reported symptoms of tachycardia, agitation, and seizures.[260] Rhabdomyolysis has also been reported.[225] Hyponatremia has been documented in patients taking as little as "one-half tablet" of the drug (tablets of ecstasy usually contain 50–150 mg of MDMA).[227] Serum sodium concentrations tend to normalize within 24 hours after the initial presentation, although symptoms including drowsiness and disorientation may persist for several days.[227]

To diagnose SIADH the clinician must exclude other causes of hyponatremia. As described above, patients with SIADH present with a euvolemic, hypotonic hyponatremia. Serum concentrations of ADH are inappropriately high for the patient's serum osmolality. As a result, the urine is inappropriately concentrated, with urine osmolality >100 mOsm/kg water and sodium >40 mEq/L with a normal sodium intake. To make a definitive diagnosis of SIADH, the patient must also have normal renal, adrenal, and thyroid function, as abnormalities in these systems can also cause a euvolemic hyponatremia.[1,3,266]

Most cases of SIADH are not drug-related, and clinicians must be alert to other potential causes so that a drug is not incorrectly identified as the culprit.[3,5] Conditions to consider in the differential diagnosis of drug-induced SIADH are listed in **Table 43-3**.

Table 43-3 Conditions to Consider in the Differential Diagnosis of Drug-Induced Syndrome of Inappropriate Antidiuretic Hormone Secretion[3,6]

- Alcohol withdrawal
- Acquired immunodeficiency syndrome
- Endocrine disorders
    - Glucocorticoid deficiency
    - Hypothyroidism
- Hereditary SIADH
- Idiopathic SIADH
- Malignant tumors
    - Bladder, ureter
    - Duodenum
    - Ovary
    - Pancreas
    - Small-cell lung
- Neuropsychiatric disorders
    - Head trauma
    - Infections
    - Neoplasms
    - Psychosis

  - Stroke, vascular
- Pain
- Postoperative state
- Pulmonary disorders
  - Functional (asthma, acute respiratory failure, mechanical ventilation)
  - Infection
- Severe nausea

When evaluating a patient with hyponatremia, the clinician must also exclude many common causes of non-SIADH hyponatremia, including the patient's use of thiazide diuretics; volume depletion caused by vomiting, diarrhea, or laxative abuse; and volume expansion that may occur in patients with cirrhosis, heart failure, and the nephritic syndrome. Although psychogenic polydipsia can also cause euvolemic hyponatremia and patients may present very much like those with SIADH, urinalysis in these patients reveals an appropriately dilute urine.

RISK FACTORS

Risk factors for drug-induced SIADH are presented in **Table 43-4**. Risk factors identified for hyponatremia due to the SSRIs include older age, concurrent diuretic use, high serum potassium concentration, female sex, lower baseline serum sodium concentration (<139 mEq/L), thiazide use, salt-restricted diet, and lower body-mass index.[15,56,114,252,267-270] At least one study failed to detect a relationship between plasma paroxetine concentrations and serum sodium concentrations.[56] Advanced age is a very important risk factor. One review of published case reports and individual reports to the U.S. Food and Drug Administration (FDA) identified 70 cases of hyponatremia associated with the SSRIs.[268] Eighty-four percent of these patients were elderly (>65 years), with a mean age of 70 years. Elevated serum potassium concentration was identified as a risk factor for SIADH in one study.[252] The majority of cases of SIADH associated with SSRIs occur in women, but it is unclear whether this is due simply to an increased exposure to the drug class as compared with men. The risk for SIADH appears to be highest in the first few weeks of therapy.[271,272] SSRIs appear to be associated with a higher risk of hyponatremia as compared with the older antidepressant agents. The risk of SIADH associated with the SSRIs has been reported to be 3.3–3.5 times greater than that with other antidepressants, although one of the trials included venlafaxine with the SSRIs in the analysis.[252,253] It has been suggested that SSRI-associated SIADH may be attributed to high serum drug concentrations.[25] However, there does not appear to be a relationship between the rate of drug metabolism or serum drug concentration and the severity of hyponatremia.[273]

Table 43-4 Risk Factors for Drug-Induced Syndrome of Inappropriate Antidiuretic Hormone Secretion

For patients taking selective serotonin-reuptake inhibitors

- Advanced age (≥65 yr)
- Baseline serum sodium concentration <139 mEq/L
- Concomitant diuretic administration
- Concomitant use of thiazide diuretics
- Elevated serum potassium concentration
- Female sex
- Lower body-mass index
- Salt-restricted diet

For patients taking carbamazepine or oxcarbazepine

- Advanced age
- Concomitant use of levetiracetam (oxcarbazepine)
- Elevated serum concentrations (carbamazepine)
- Higher doses (carbamazepine)

For patients taking vincristine, vinblastine

- Asian race

Hyponatremia due to carbamazepine may be related to higher doses and elevated serum concentrations, as doses >30 mg/kg/day have been associated with a higher incidence of hyponatremia.[164,259] Hyponatremia occurred in a patient previously stable on carbamazepine when clarithromycin was prescribed.[169] Presumably, the clarithromycin increased serum carbamazepine concentrations, causing hyponatremia, further supporting a concentration-related effect. Concomitant use of levetiracetam may increase the risk for hyponatremia with oxcarbazepine, while sex likely is not a risk factor.[170] It has been reported that hyponatremia due to oxcarbazepine occurs more commonly in patients older than 65 years of age (7.3%) as compared with children younger than 17 years of age (0.4%).[259] However, one noncontrolled trial indicated that 26.6% of children and adolescents experience hyponatremia (with serum sodium concentrations <135 mEq/L) in association with oxcarbazepine. Hyponatremia with serum sodium concentrations <125 mEq/L occurred in 2.6% of the patients.[163]

A review of the manufacturer's database of adverse drug reactions suggests that Asians may be at higher risk for SIADH induced by vincristine; of the 39 cases that included information on race, 35 patients were Asian. A similar relationship between Asian race and SIADH was found with vinblastine.[159]

Many of the initial case reports of hyponatremia associated with MDMA occurred in women, leading some to suggest that women may be at higher risk.[225] Although one series of case reports found an equal distribution between men and women, a more recent, larger study suggested that women are more likely to experience hyponatremia after MDMA ingestion.[227,260]

MORBIDITY AND MORTALITY

Many patients with drug-induced SIADH probably have mild hyponatremia that is asymptomatic and goes undetected. The published reports include more severe cases, in which patients experience symptoms including encephalopathy and seizures.[40,167,182] Most patients with drug-induced SIADH recover fully, but at least six deaths due to MDMA-induced hyponatremia have been reported.[227,229,274] In 545 cases of MDMA intoxication reported to a poison control center in California, 13 patients died.[260] Deaths due to SIADH associated with cyclophosphamide and carbamazepine have also been reported.[146,275]

PREVENTION

Although there are no universally accepted recommendations for prevention of drug-induced SIADH, some strategies that may help are listed in **Table 43-5**. It is always wise to use the lowest possible therapeutic dose of drugs with the potential to induce SIADH. Specific guidelines for monitoring serum sodium concentrations are not available. It has been suggested, however, that patients with risk factors for SSRI-induced hyponatremia (Table 43-4) should have serum sodium concentrations measured 1 and 2 weeks after the initiation of treatment.[56]

Table 43-5 Approaches to Help Prevent Drug-Induced Syndrome of Inappropriate Antidiuretic Hormone Secretion

- Use lowest possible dose of drugs with potential to induce SIADH
- Patients at risk should have serum sodium determinations 1 and 2 weeks after initiation of treatment

MANAGEMENT

Treatment strategies for drug-induced SIADH are presented in **Table 43-6**. If drug-induced SIADH is suspected, the offending agent should be discontinued whenever possible. Most patients with drug-induced SIADH have chronic, asymptomatic hyponatremia, and in this situation, water restriction (500–1,000 mL/day) should be initiated. This may allow the serum sodium concentration to normalize. Furosemide (20–40 mg orally or intravenously every 12–24 hours) can be used to increase free water excretion; simultaneous replacement of salt and volume should be performed as needed using 0.9% sodium chloride solution. Although central nervous system symptoms are fairly rare in drug-induced SIADH, when present, treatment should be initiated with hypertonic saline to raise the serum sodium concentration. The goal of therapy is to reverse neurologic symptoms and raise the serum sodium concentration by 1–2 mEq/L/hr. The use of hypertonic saline requires close monitoring and infusion should be discontinued when the serum sodium concentration increases by 10–12 mEq/L or to 130 mEq/L.[266,276] If hyponatremia correction is too rapid, osmotic demyelination may occur.[266]

Table 43-6 Treatment Options for Drug-Induced Syndrome of Inappropriate Antidiuretic Hormone Secretion

- Demeclocycline (150–300 mg 3 times daily)
- Discontinue offending agent
- Hypertonic saline (symptomatic hyponatremia only)
- Isotonic saline
- Loop diuretic (furosemide 20–40 mg orally or intravenously every 12–24 hours)
- Vasopressin antagonists (conivaptan or tolvaptan)
- Water restriction (500–1,000 mL/day)

Vasopressin-receptor antagonists offer a relatively new approach in the management of hyponatremia, including that which occurs as a result of SIADH. Antagonism of the arginine vasopressin receptor V_2 results in increased renal elimination of free water, with a resultant increase in the serum sodium concentration. Conivaptan is an FDA-approved intravenous vasopressin-receptor antagonist for the treatment of euvolemic hyponatremia in hospitalized patients, including those with SIADH, hypothyroidism, adrenal disorders, and pulmonary disorders.[277] Tolvaptan is an orally administered vasopressin-receptor antagonist that received FDA approval for use in the treatment of euvolemic or hypervolemic (i.e., heart failure) hyponatremia. Although these medications are effective in SIADH, they have not been studied specifically for the treatment of drug-induced SIADH, and the role of these agents is likely limited. Most patients respond well to discontinuation of the offending agent; in addition, the high cost of the vasopressin antagonists will likely deter their use.

Expert panels have published recommendations for the treatment of hyponatremia.[278,279] A panel supported by Otsuka, the manufacturer of tolvaptan, supports the use of vasopressin antagonists in patients with SIADH in situations where fluid restriction has failed. A second expert panel (the European Practice Guideline)[280] does not recommend the use of the vasopressin antagonists in euvolemic patients with SIADH and noted the paucity of survival benefit with the vasopressin antagonists.[281]

In cases of SSRI-induced SIADH, it is probably not appropriate to substitute a different drug within the same class, as cross-sensitivity has been documented.[24,29,41] It is unknown whether dose reduction is beneficial. Venlafaxine should not be used in these patients, as this drug has been reported to cause hyponatremia in a patient with previously diagnosed SSRI-induced SIADH.[14,52] Recurrence of hyponatremia has also been reported with switches from citalopram to mirtazapine and from citalopram to duloxetine although a switch from citalopram to mirtazapine proved to be safe.[9,18,19] Bupropion-induced SIADH has been reported in a patient who previously experienced imipramine-induced SIADH.[94] However, bupropion was used safely in another patient with a history of SSRI-induced SIADH.[90] Hyponatremia did not recur when doxepin was administered to a patient with imipramine-induced SIADH.[92]

Although haloperidol has been reported to cause SIADH, it was administered safely to a patient who had previously experienced risperidone-induced SIADH.[123,124,130] Clozapine has been reported to cause hyponatremia, although SIADH was not definitively diagnosed.[121] Of note, clozapine has been used effectively to manage hyponatremia associated with psychogenic polydipsia, presumably by managing the underlying psychological disorder.[282,283]

A 12-year-old girl who developed symptomatic hyponatremia after exposure to oxcarbazepine did not experience recurrence of hyponatremia when carbamazepine was substituted.[284] Nevertheless, careful monitoring of serum sodium concentrations is warranted if carbamazepine is to be used in a patient who has had oxcarbazepine-induced SIADH.

Demeclocycline (oral: 600–1,200 mg/day) has been used for chronic SIADH, and both doxycycline (100 mg orally twice daily) and demeclocycline (300 mg orally twice daily for 3–5 days then 600 mg twice daily) have been used to treat hyponatremia associated with carbamazepine.[2,162,285] Demeclocycline has been found to be effective for the prevention of vinorelbine-induced SIADH.[67] Despite these successes, there is a paucity of clinical and economic evidence to support the use of demeclocycline for hyponatremia secondary to SIADH.[286]

INFORMATION FOR PATIENTS

Although SIADH is relatively rare, medications including psychotropics, antihypertensives, chemotherapy agents, and anticonvulsants can cause SIADH. Patients at risk for the development of SIADH, particularly the elderly, should be advised to avoid excessive intake of fluids when starting therapy with a drug known to cause this drug-induced disease. Individuals who use MDMA (ecstasy) tend to have more acute episodes of hyponatremia because they sometimes “water-load” to prevent hyperthermia associated with this drug. Unfortunately, water loading leads to more serious episodes of hyponatremia. Consequently, individuals who use MDMA should avoid ingesting excessive amounts of fluid.

DRUG-INDUCED DIABETES INSIPIDUS

CAUSATIVE AGENTS

Nephrogenic diabetes insipidus is manifested by diminished ability to concentrate the urine resulting from resistance to AVP. Except in the case of olanzapine, drug-induced diabetes insipidus (DI) is always nephrogenic.[2] Although lithium is the most important cause of drug-induced DI, other agents implicated are included in **Table 43-7**. In three patients in whom amphotericin B–induced DI developed, the disease did not recur when liposomal amphotericin therapy was substituted.[288,290] However, the first report of a DI related to liposomal amphotericin involved a patient who was not previously receiving conventional amphotericin therapy.[291] In the cases of mesalamine-induced and rifampin-induced DI, an acute interstitial nephritis was also present.[325] Although 10 reports of clozapine-induced nephrogenic DI were identified from the World Health Organization's database of adverse drug reactions, none have been reported in the literature.[294,330]

Table 43-7 Agents Implicated in Drug-Induced Diabetes Insipidus

Drug	Incidence	Level of Evidence[a]
Amiodarone[287]	NK	C

Triamterene/hydrochlorothiazide[336]	NK	C
Voriconazole[337]	<2%	B

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] Presents as central diabetes insipidus.

EPIDEMIOLOGY

By far, the most common culprit in drug-induced DI is lithium. The incidence of DI in patients receiving lithium has been estimated at 15–87%.[294] A retrospective study of 142 patients receiving long-term lithium therapy found an incidence of DI of 12%.[310] Limited case reports of DI caused by drugs other than lithium don’t permit estimates of incidence.

MECHANISMS

Drug-induced nephrogenic DI is caused by inhibition of the opening of aquaporins (water-transport channels) in nephrons, with resultant polyuria. The exact mechanism is complex and not completely understood. In rat models, lithium administration has been associated with a reduced expression of the aquaporin-2 receptor. The specific action of lithium on the aquaporins may be related to antagonism of adenylate cyclase and cyclic adenosine monophosphate.[338] Central DI is caused by impaired production of AVP and may be acquired (head trauma) or congenital (hereditary).

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Both central and nephrogenic DI are characterized by the production of inappropriately large amounts of dilute urine (urinary osmolality <250 mOsm/kg water). Polyuria results in increased thirst (polydipsia). If there is not appropriate access to or administration of free water, hypernatremia and dehydration occur within hours. Symptoms of hypernatremia are related to cellular dehydration because of the movement of water out of cells and, like those of hyponatremia, are primarily neurologic and include altered mental status, weakness, lethargy, and occasionally coma or seizures (**Table 43-8**). Severe acute hypernatremia can result in death.[1-3] Although generally reversible, some permanent urine-concentrating defects can occur after prolonged exposure to lithium.[339] DI can occur at any time after lithium initiation but generally occurs after long-term exposure (>15 years).

Table 43-8 Signs and Symptoms Associated with Drug-Induced Diabetes Insipidus (Hypernatremia)[1-3]

- Altered mental status
- Coma
- Fever
- Focal neurologic deficits
- Nausea
- Neuromuscular irritability
- Seizures
- Thirst
- Vomiting
- Weakness

As with SIADH, DI is diagnosed by excluding other causes of disordered sodium homeostasis. If adequate fluid intake is not maintained, patients with central or nephrogenic DI present with a euvolemic, hypertonic hypernatremia. The urine is inappropriately dilute (urine osmolality <250 mOsm/kg water) given the hypertonicity of the plasma. The diagnosis of DI can be made by measuring the urine-concentrating ability of the kidney during a water-deprivation test.[294] After 3–

6 hours of water deprivation, patients with DI continue to produce large amounts of dilute urine (urine osmolality <400 mOsm/kg water). During this test, central and nephrogenic DI can generally be differentiated by patients' response to desmopressin (1-deamino-8-D-arginine vasopressin). In patients with nephrogenic DI, desmopressin administration (5 units of aqueous vasopressin subcutaneously or 10 mcg of intranasal desmopressin) does not result in the production of a concentrated urine, in contrast to patients with central DI. Hypernatremia due to DI must be distinguished from other causes, such as insensible water loss and gastrointestinal and renal losses. Patients with insensible water loss or gastrointestinal or renal losses generally are hypovolemic. In addition, these patients usually have maximally concentrated urine, owing to an appropriate action of ADH in the nephron. Conditions to consider in the differential diagnosis of drug-induced DI are listed in **Table 43-9**.

Table 43-9 Conditions to Consider in the Differential Diagnosis of Diabetes Insipidus

Central diabetes insipidus

- Head trauma
- Hypoxic or ischemic encephalopathy
- Idiopathic diabetes insipidus
- Neoplasm
- Neurosurgery
- Miscellaneous (histiocytosis X, sarcoidosis, anorexia nervosa, cerebral aneurysm, encephalitis, meningitis)

Nephrogenic diabetes insipidus

- Amyloidosis
- Congenital diabetes insipidus
- Hypercalcemia
- Hypokalemia
- Osmotic diuresis (glucose, mannitol)
- Pregnancy
- Renal failure
- Sickle-cell anemia
- Sjögren syndrome

RISK FACTORS

Proposed risk factors for lithium-induced nephrogenic DI are presented in **Table 43-10** and include chronic kidney disease (estimated creatinine clearance <60 mL/min), multiple daily doses (versus a once-daily regimen), long treatment durations (>15 years), and higher trough serum lithium concentrations.[294,340-342] It should be noted, however, that many of the studies used to define these risk factors were relatively small and some produced contradictory information.

Table 43-10 Risk Factors for Lithium-Induced Diabetes Insipidus

- Chronic kidney disease (estimated creatinine clearance <60 mL/min)
- Higher trough serum lithium concentrations
- Long treatment durations (>15 yr)
- Multiple daily doses (vs. a once-daily regimen)

MORBIDITY AND MORTALITY

Impaired urinary concentrating ability can occur in up to 20% of patients receiving chronic lithium therapy. Drug-induced SI is often reversible. Although the impact of drug-induced DI on health and quality of life can be significant, there have been only three case reports of death due to lithium-induced nephrogenic DI.[229,294]

PREVENTION

Some general strategies to reduce the likelihood of lithium-induced DI are listed in **Table 43-11**. Use of the lowest possible dose is critical to reducing the risk of lithium-induced DI. Trough serum lithium concentrations should be 0.6–1.0 mEq/L, and serum concentrations >1 mEq/L should definitely be avoided.[294] Administration of lithium as a once-daily regimen, administration of lower total daily doses, or both can reduce the risk of lithium-induced DI.[341]

Table 43-11 Approaches to Help Prevent Lithium-Induced Diabetes Insipidus

- Administer once daily
- Trough serum concentrations should be 0.4–0.6 mEq/L Avoid serum concentrations >1 mEq/L
- Use lowest possible dose

MANAGEMENT

Strategies for the treatment of drug-induced nephrogenic DI are outlined in **Table 43-12**. The offending agent should be discontinued if possible. The polyuria associated with lithium usually resolves within a few weeks after discontinuation, although nonreversible DI is a possibility.[294,311] If patients have access to water and are neurologically competent, hypernatremia will not occur, as patients will drink to quench thirst. Mild cases of nephrogenic DI can be managed with sufficient adequate water intake. Low-sodium diet may reduce water excretion. In some cases, a reduction of the lithium dose may control the polyuria; however, discontinuation of lithium and initiation of an alternative therapy may be necessary.[294] The potassium-sparing diuretic amiloride, at doses of 10–20 mg daily, has been shown to reduce urinary output in patients with lithium-induced DI.[308,317] Amiloride may be preferable to hydrochlorothiazide because of its potassium-sparing effect and reduced propensity to cause volume depletion (which can induce or exacerbate lithium toxicity).[294] In one case of foscarnet-induced DI, treatment with amiloride was not successful in reducing polyuria.[303] Lithium-induced DI has been managed with indomethacin (50 mg every 8 hours).[311,313,315,316] It should be noted, however, that indomethacin can impair kidney function.[313]

Table 43-12 Treatment Options for Drug-Induced Diabetes Insipidus

- Amiloride (10–20 mg daily)
- Discontinue offending agent
- Hydrochlorothiazide (25 mg once or twice daily)
- Indomethacin (50 mg every 8 hours)
- Water administration (allow free access)

INFORMATION FOR PATIENTS

Patients receiving therapy with lithium and their caregivers should be informed regarding the need to monitor for increased urinary output and excessive thirst. Patients should be instructed to report excessive urination and urine volumes to their healthcare provider.

Note: The authors wish to acknowledge the work of Dr. Nayahmka McGriff-Lee, who authored this chapter in a previous edition.

CHAPTER 44

Acid–Base Disorders

Lori D. Wazny, J. Christine Davis, and Robert E. Ariano

Acid–base balance can be defined as homeostasis of body fluids at a normal arterial blood pH between 7.35 and 7.45. Clinicians must be able to anticipate and help avoid or minimize the clinical consequences of drug-induced acid–base disorders, and, when that is not possible, they must be able to design appropriate treatment regimens to correct the abnormality.[1] A skilled clinician can play a significant role in the prevention, identification, and management of potentially life-threatening drug-induced disturbances in acid–base balance.

ACIDOSIS

CAUSATIVE AGENTS

Drugs that have been reported to cause metabolic or respiratory acidosis are listed in **Table 44-1**. Drug-induced metabolic acidosis is caused by acid accumulation from increased acid production or acid ingestion; decreased acid excretion; or gastrointestinal (GI) or renal bicarbonate loss. Drug-induced respiratory acidosis is caused by either depression of the central respiratory center leading to decreased ventilation and accumulation of carbon dioxide (CO_2) or increased CO_2 production as might occur, for example, with overfeeding during nutritional support.

EPIDEMIOLOGY

Overall, the incidence of drug-induced acidosis is largely unknown, with the majority of evidence limited to case reports, case series, or open-label studies. Unintentional overdosage of central respiratory depressants may occur in the hospital setting, but published reports on the frequency of this complication or the number of patients in whom a clinically significant respiratory acidosis develops as a result are not available.

MECHANISMS

Mechanisms of drug-induced acidosis, where known, are noted in Table 44-1 and described in **Table 44-2**. Metabolic acidosis is caused by acid accumulation from increased acid production or acid ingestion, decreased acid excretion, or GI or renal bicarbonate loss. Acidemia (arterial pH <7.35) results when respiratory compensation (i.e., removal of CO_2 via the lungs) is overwhelmed. Determination of the anion gap (AG) is useful in distinguishing the type of metabolic acidosis. It is calculated by subtracting the sum of the serum chloride (Cl^-) and bicarbonate (HCO_3^-) concentrations from the serum sodium (Na^+) concentration:

$$AG = ([Na^+]) - ([Cl^-] + [HCO_3^-])$$

Table 44-1 Agents Implicated in Drug-Induced Acidosis

Drug	Incidence	Level of Evidence[a]
ELEVATED ANION-GAP METABOLIC ACIDOSIS		
Lactic Acidosis		
Amygdalin[39,40]	NK	C
Antibacterial-induced D-lactic acidosis (tetracycline, metronidazole) in patients post intestinal bypass surgery or small bowel resection[41,42]	NK	C
β_2 agonists (albuterol, salbutamol, theophylline)[43-47]	NK	C
	3–10 per 100,000 patient years for	B

Biguanides: metformin,[b] phenformin,[b] buformin[42]	metformin, higher incidences for phenformin and buformin[48-50]	
Catecholamines (epinephrine, norepinephrine)[51,52]	NK	C
Isoniazid overdose >30 mg/kg[53,54]	NK	C
Linezolid[55,56]	NK	C
Nalidixic acid overdose[57]	NK	C
Niacin[42]	NK	C
Nitroprusside[58]	NK	C
Nucleoside reverse transcriptase inhibitors (didanosine, lamivudine, stavudine, zidovudine)[42]	1.3–10 cases/1,000 patient years Didanosine>stavudine>zidovudine[59]	B
Propylene glycol containing IV medications (Table 44-7)	NK	C
Propofol[60,61]	24%[42]	B
Rhabdomyolysis induced by statins, fibric acids, or neuroleptic malignant syndrome[42]	NK	C
Sorbitol and xylitol[62,63]	NK	C
Topical emollients containing lactic acid[64]	NK	C
Ketoacidosis		
Atypical antipsychotics (aripiprazole, clozapine, olanzapine, risperidone, quetiapine)[65,66]	NK	C
Salicylate overdose (mixed disorder: metabolic acidosis + respiratory alkalosis)[67,68]	NK	C
Sodium-glucose cotransporter 2 (SGLT2) inhibitors (canagliflozin, dapagliflozin, empagliflozin)[69]	NK	C
Addition of Unmeasured Anions		
Acetaminophen[70,71]	NK	C
Sodium thiosulfate[72]	NK	C
Other		
Ibuprofen overdose[73]	NK	C
Iron overdose[1]	NK	C
Papaverine[74]	NK	C
NORMAL ANION-GAP METABOLIC ACIDOSIS		
Cholestyramine (GI HCO_3 loss)[75,76]	NK	C
Laxative abuse-induced diarrhea (GI HCO_3 loss)[77]	NK	C
Sevelamer hydrochloride (not carbonate)[78,79]	22%	C

Rapid 0.9% NaCl administration[80] (dilutional acidosis)	NK	C
PROXIMAL (TYPE II) RENAL TUBULAR ACIDOSIS		
Aminoglycosides[42]	NK	C
Carbonic anhydrase inhibitors (e.g., acetazolamide, brinzolamide eye drop, topiramate, zonisamide)[42]	Up to 55% with acetazolamide[42]; up to 48% with topiramate[42]	C
Cidofovir[81]	1%	B
Ifosfamide[42,82]	7–14%	C
Leflunomide[42]	NK	C
Mercaptopurine[42]	NK	C
Nucleoside reverse transcriptase inhibitors (abacavir, adefovir [high doses], didanosine, tenofovir)[42]	48% with tenofovir; 27–50% with adefovir	A
Oxaliplatin[83]	NK	C
Ranitidine[42]	NK	C
Sulfamethoxazole[84]	NK	C
Streptozocin[85]	NK	C
Tetracycline, expired[86,87]	NK	C
Valproic acid[42]	NK	C
TYPE I DISTAL RENAL TUBULAR ACIDOSIS		
Amphotericin B[84]	1%	C
Cisplatin[88]	NK	C
Foscarnet[42]	NK	C
Lithium[89]	NK	C
TYPE IV DISTAL RENAL TUBULAR ACIDOSIS		
Impaired renin release (NSAIDs, cyclosporine, tacrolimus)[42]	NK	B
RAAS blockade (ACEI, ARBs, direct renin inhibitors, e.g., aliskiren)[42]	NK	C
Impaired aldosterone metabolism (heparin)[42]	NK	C
Aldosterone antagonists (spironolactone, eplerenone)[42]	NK	C
K+ sparing diuretics (amiloride, triamterene)[42]	NK	C
Trimethoprim[84]	NK	C
RESPIRATORY ACIDOSIS[5,90]		

Central Respiratory Depression

Anesthetics	NK	C
Barbiturates	NK	B
Benzodiazepines	NK	B
Narcotics	NK	B
Increased CO_2 Production		
Parenteral or enteral nutrition (if excessive calories)	NK	B

IV = intravenous, NK = not known.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] Available in countries outside of the United States.

Table 44-2 Mechanisms of Drug-Induced Acidosis[42]

Cause	Mechanism
ELEVATED ANION GAP	
Addition of unmeasured anions	Acetaminophen: accumulation of pyroglutamic acid (5-oxoproline) Sodium thiosulfate: thiosulfuric acid produced when dissolved in aqueous solution
Ketoacidosis	Increased metabolism of fatty acids leading to increased ketone (acetoacetate, β-hydroxybutyrate) synthesis in the liver
Lactic acidosis	Increased lactate production due to either altered pyruvate conversion to lactate, increased pyruvate production, or impaired pyruvate utilization or removal Serum lactate concentrations >5 mEq/L
NORMAL ANION GAP	
Distal type I renal tubular acidosis	Selective deficiency of H^+ secretion in the distal tubule; commonly associated with hypokalemia due to renal potassium wasting
Distal type IV renal tubular acidosis	Aldosterone deficiency or antagonism impairs distal renal Na^+ reabsorption and K^+ and H^+ excretion leading to acidosis; the resulting hyperkalemia may worsen the acidosis as K^+ moves into cells and H^+ moves out
Gastrointestinal bicarbonate loss	Cholestyramine binds intestinal bicarbonate in exchange for chloride Laxative-induced diarrhea causes significant bicarbonate loss through the stool
Proximal (type II) renal tubular acidosis	Selective defect in the proximal tubule to adequately reabsorb filtered bicarbonate The bicarbonate defect may occur alone or as part of Fanconi syndrome whereby proximal tubule reabsorption of phosphate, glucose, amino acids, and uric acid is also impaired

Rapid 0.9% NaCl administration (dilutional acidosis)[80]	Nonalkali-containing IV fluids result in dilution of bicarbonate in the ECF; the condition corrects itself as the kidneys generate bicarbonate and reduce the ECF
Sevelamer hydrochloride salt	Exchanges hydrochloride for bicarbonate
RESPIRATORY ACIDOSIS	
Acute respiratory acidosis due to ↓ respiratory drive	Exposure to central nervous system depressing drugs or ↑ production of CO_2 from overfeeding during nutritional support

CO_2 = carbon dioxide, ECF = extracellular fluid, H = hydrogen, IV = intravenous, K = potassium, Na = sodium, NaCl = sodium chloride.

The normal range for the AG may differ among laboratories, and clinicians should consider their particular laboratory's reference range when assessing this value. In general, an elevated AG is >12 mEq/L.

Metabolic acidosis with an elevated AG can be caused by endogenous (lactate, ketones, myoglobin, uremia) or exogenous (methanol, ethylene glycol, propylene glycol, salicylates) substances. The majority of elevated AG metabolic acidoses due to prescription drugs are a result of lactic acidosis, although some drugs (e.g., acetaminophen, sodium thiosulfate) cause acidosis by adding unmeasured anions.

Metabolic acidosis with a normal AG is caused either by gastrointestinal loss of bicarbonate or by renal loss of bicarbonate (e.g., renal tubular acidosis [RTA]). RTA is a defect of urinary acidification occurring in either the proximal or the distal renal tubule. Proximal (Type II) RTA involves a failure in proximal tubule reabsorption of filtered bicarbonate; distal RTA is characterized by impaired acid excretion. Distal RTA is subdivided into that associated with hypokalemia (Type I) and that associated with hyperkalemia (Type IV). Drugs may be implicated as causative agents in any of these RTA types, but the mechanism by which drugs cause RTA in most cases is either not known or incompletely understood. Readers are referred to the references listed in Table 44-1 for more specific details regarding the proposed mechanisms behind a specific drug-induced RTA.

Respiratory acidosis is the result of an accumulation of CO_2 in the blood. Accumulation may occur for several reasons: (1) decreased excretion by a depressed respiratory drive, abnormal neuromuscular transmission, or muscle dysfunction all resulting in alveolar hypoventilation; (2) decreased removal of CO_2 as is seen with obstructive pulmonary disorders or ventilation–perfusion mismatches; and/or, (3) an increased production of CO_2. Irrespective of the etiology, the accumulation of CO_2 within plasma water promptly forms carbonic acid and subsequent acidemia.

Respiratory acidosis may be classified as either acute or chronic. The absence of normal physiologic compensation defines an acute process. The normal compensatory response to respiratory acidosis requires the metabolic system (i.e., the kidney) to retain bicarbonate to partially correct the acidemia. Renal compensation for respiratory acidosis is slow, however, (taking hours to days) so the hallmarks of this acid–base disorder include an acidemia (pH <7.35) with an elevated carbon dioxide ($paCO_2$) above the reference range of 45 mm Hg and a serum bicarbonate level within the normal range (22–28 mEq/L). In contrast, patients with chronic respiratory acidosis will present with an acidemia >24 hours in duration, an elevated $paCO_2$, and a significantly elevated serum bicarbonate level (>30 mEq/L).[2] Elevated $paCO_2$ mediates bicarbonate retention through the renal production of ammonia. Generated ammonia binds and titrates down serum chloride to form ammonium chloride, which is then excreted renally causing hypochloremia. There is renal retention of bicarbonate and sodium as a consequence of urinary ammonium chloride losses. Thus the acidemia from respiratory acidosis is partially corrected by the slow retention of bicarbonate.[3]

Acute respiratory acidosis may be the result of reduced respiratory drive from central nervous system–depressing drugs like narcotics and sedatives or from overfeeding during nutritional support. It may also arise from neuromuscular weakness disorders (myasthenia gravis, acute Guillain-Barré syndrome, or high cervical cord lesions) and from acute cardiopulmonary disorders such as exacerbations of chronic obstructive pulmonary disease (COPD), pulmonary edema, and acute respiratory distress syndrome.[4] Generally, drug-induced respiratory acidosis is an acute process.

Patients with acute respiratory acidosis typically present with ventilatory failure leading to hypercapnea and hypoxemia. A useful method to determine whether or not acute hypoxemia is due to reduced respiratory drive is to measure the alveolar–arterial oxygen gradient [$P(A\text{-}a)O_2$]. The $P(A\text{-}a)O_2$ gradient is helpful in assessing the efficiency of alveolar-capillary gas exchange. An elevated $P(A\text{-}a) O_2$ gradient suggests parenchymal lung disease with either a ventilation–perfusion imbalance or intrapulmonary shunting. Drug-induced acute respiratory acidosis commonly presents with a normal $P(A\text{-}a) O_2$ gradient.

An increased production of CO_2 may be the result of hypercatabolic states such as sepsis or malignant hyperthermia or the result of overfeeding during nutritional support. Carbohydrate overfeeding has often been identified as a cause of hypercapnia and respiratory acidosis.[5] Evidence has shown, however, that it is not actually high carbohydrate administration that increases CO_2 production, rather it is the total calories delivered. CO_2 increases when the caloric intake exceeds the rate of carbohydrate metabolism, and CO_2 production remains constant when the proportion of total calories delivered as carbohydrates is reduced.[6] Excessive CO_2

production from overfeeding is associated with prolonged weaning from mechanical ventilation, especially when the ventilatory rate is fixed.[7]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

General features of metabolic acidosis include an increase in ventilation, a decrease in central and pulmonary vascular compliance predisposing to pulmonary edema with even minimal volume overload, and depression of central nervous function. Acidosis is usually first suspected as a result of the discovery of abnormalities in arterial blood gases or electrolytes, which then leads to evaluation of the AG.[8] Screening to identify drug-induced metabolic acidosis should include a thorough medication history to uncover evidence of exposure to potential causative agents and, in patients who present with an elevated AG, determination of the serum lactate concentration.

Signs and symptoms associated with drug-induced metabolic acidosis are listed in **Table 44-3**. Mild acidemia is generally asymptomatic; however, as acidemia becomes more severe, patients may experience nausea, vomiting, loss of appetite, and abdominal pain. These symptoms may appear at higher pH if acidosis develops rapidly. The most characteristic sign is hyperpnea, which leads to Kussmaul breathing, a deep and labored breathing pattern reflecting a compensatory increase in alveolar ventilation. Severe, acute acidosis predisposes to reduced cardiac output, hypotension and shock, ventricular arrhythmias, and coma. Chronic acidosis can cause bone demineralization and osteoporosis.

Table 44-3 Signs and Symptoms Associated with Drug-Induced Acidosis[1,91]

Signs	***Symptoms***
MILD TO MODERATE METABOLIC ACIDOSIS (pH 7.1–7.35)	
• Hyperkalemia • Serum lactate concentration ≥5 mEq/L (lactic acidosis) • Tachycardia	• Abdominal pain • Flushing • Hyperventilation/Kussmaul respirations • Loss of appetite • Nausea and Vomiting
SEVERE METABOLIC ACIDOSIS (pH <7.1)	
• Hyperglycemia • Hypotension • Multisystem organ failure	• Obtundation and coma
ACUTE RESPIRATORY ACIDOSIS	
• Asterixis	• Disorientation

• Coma • Combativeness • Congestive heart failure/cardiogenic shock (if severe hypercapnia develops) • Increased intracranial pressure (pseudotumor cerebri) • Myoclonic jerks • Seizures • Stupor • Tremor	• Drowsiness • Severe breathlessness • Confusion • Headache • Anxiety

Conditions to consider in the differential diagnosis of metabolic acidosis are listed in **Table 44-4**. The differential diagnosis of metabolic acidosis in patients with a normal AG includes GI bicarbonate loss and renal tubular acidification defects. Calculation of the urine anion gap (UAG) is helpful in distinguishing between bicarbonate loss occurring via the GI tract or via the kidneys:

$$\text{UAG} = [\text{Urine}_{\text{Na}} + \text{Urine}_{\text{K}}] - \text{Urine}_{\text{Cl}}$$

When bicarbonate is lost via the GI tract, the UAG is negative. When the kidneys are unable to generate sufficient amounts of ammonium or when loss of bicarbonate through the kidney occurs, the UAG is zero or positive.[8] Calculation of fractional bicarbonate excretion (FE-HCO_3) can help differentiate between distal and proximal RTA. FE-HCO_3 is calculated as:

$$\text{FE-HCO}_3 = (\text{uHCO}_3 \times \text{sCr}) / (\text{sHCO}_3 \times \text{uCr})$$

where uHCO_3 is urine bicarbonate concentration, sHCO_3 is serum bicarbonate concentration, uCr is urine creatinine concentration, and sCr is serum creatinine concentration.

An FE–HCO_3 <0.05 indicates distal RTA, whereas an FE–HCO_3 >0.15 is indicative of proximal RTA, assuming in both instances that serum bicarbonate is >20 mEq/L.

Signs and symptoms of respiratory acidosis (Table 44-3) vary depending on the rate and degree of CO_2 increase and are typically the result of high CO_2 concentrations in the central nervous system and hypoxemia, if present. Acute respiratory acidosis may cause headache, confusion, anxiety, drowsiness, seizure, and stupor. Patients with respiratory acidosis that develops slowly over time typically display minimal symptoms but may experience memory loss, sleep disturbances, excessive daytime sleepiness, and personality changes. Conditions to consider in the differential diagnosis of drug-induced respiratory acidosis are listed in Table 44-4. Patient evaluation should include a careful medication history, examination of the arterial blood gases, hematocrit measurement, chest x-ray, an assessment of the upper airways, and evaluation of respiratory and neuromuscular function.

Table 44-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Acidosis[2,91-93,a]

Anion gap metabolic acidosis

Diabetic or alcoholic ketoacidosis
Ethylene glycol
Lactic acidosis
Methanol
Uremia

Non-anion-gap metabolic acidosis

Diarrhea
Pancreatic fistula
Parenteral hyperalimentation
Renal tubular acidosis (RTA)
Ureteroenterostomy

Respiratory acidosis—acute and chronic

Depressed central respiratory drive

- Brain-stem lesion, or tumor
- Central sleep apnea (C)
- Cerebral edema
- Cerebrovascular accident
- Encephalitis
- Head trauma
- Hypothyroidism (C)
- Obesity hypoventilation syndrome

Abnormal neuromuscular transmission

- Amytrophic lateral sclerosis (C)
- Guillain–Barré syndrome
- Multiple sclerosis (C)
- Muscle dysfunction
- Muscular dystrophy (C)
    - Fatigue
    - Hyperkalemia
    - Hypokalemia
- Myasthenia gravis
- Polymyositis (C)
- Status epilepticus

Enhanced ventilatory demand

- Failure of CO_2 transport
  - o Pulmonary embolism
  - o Cardiac arrest
- High caloric intake
- Increased dead space ventilation

Ventilation/perfusion mismatch

- Acute lung injury/acute respiratory distress syndrome
- Angioedema
- Augmented airway flow resistance
- Chronic obstructive pulmonary disease
- Emphysema (C)
- Pulmonary fibrosis (C)
- Severe pneumonia
- Status asthmaticus
- Upper airway obstruction

Pleural/chest wall/lung stiffness

- Abdominal distension
- Atelectasis
- Chest wall trauma with flail chest
- Kyphoscoliosis (C)
- Obesity (C)
- Pneumothorax

---

a(C) defines chronic respiratory acidosis etiologies only. All others may present either acutely or chronically.

RISK FACTORS

Table 44-5 lists risk factors for drug-induced acidosis. Drug-induced respiratory depression is typically dose-related, and higher doses lead to increased risk of respiratory acidosis, but the data supporting dose-dependency primarily derive from the literature with respect to narcotics.[9]

MORBIDITY AND MORTALITY

The risk of morbidity and mortality associated with drug-induced metabolic or respiratory acidosis has not been quantified in most cases. However, mortality data are available for metabolic acidosis, specifically lactic acidosis, induced by nucleoside reverse-transcriptase inhibitors (NRTIs) (33–57% mortality), metformin (45–50% mortality), and propofol (65% mortality).[10-14]

PREVENTION

General strategies for the prevention of drug-induced acidosis are listed in **Table 44-6**. Overall, strategies are aimed at identifying patients at risk and educating both patients and heathcare professionals to help promote early recognition. More specific preventative measures have been suggested for lactic acidosis due to propylene glycol and propofol. Patients receiving continuous intravenous infusions of products containing propylene glycol (**Table 44-7**) for more than 2–5 days should be carefully monitored. Serum osmolality should be measured twice weekly (propylene glycol contributes to osmolality), and alternative therapeutic agents should be considered when the serum osmolality is >320 mOsm/kg.[15] Propofol infusion rates of >4–5 mg/kg/hr for longer than 48 hours should also be avoided.[13,14]

Table 44-5 Risk Factors for Drug-Induced Acidosis[42,76,94]

Metabolic acidosis

General risks

- Cirrhosis
- Diabetes
- Extracellular fluid volume depletion
- Heart failure
- Renal dysfunction

Drug risks

- Acetaminophen: Renal or hepatic insufficiency, alcoholism, female sex, chronic ingestion
- Aminoglycosides: High doses, prolonged administration
- Amphotericin B: Cumulative doses of >2–3 g
- Cholestyramine: Renal insufficiency, volume depletion, combination with spironolactone; co-administration of more than one drug implicated in drug-induced acidosis
- Ifosfamide: Total dose >100 g/m^2, administration with other nephrotoxic drugs
- Metformin: Renal insufficiency (eGFR <30 mL/min/1.73 m^2), hepatic insufficiency, history of lactic acidosis, hypoxia or serious illness, cardiovascular or pulmonary dysfunction, IV contrast agent exposure
- Niacin: High doses, co-ingestion with alcohol
- NRTI-induced lactic acidosis: Co-infection with hepatitis B or C, more than one antiretroviral drug, more than one drug known to cause lactic acidosis, female sex, renal insufficiency, low CD4 count, obesity, pregnancy
- Propofol: Infusion rates >4 mg/kg/hr, duration of infusion >48 hr, concomitant use of catecholamines or corticosteroids, age <18 years, sepsis, head injury
- Propylene glycol–containing drugs: Renal or hepatic insufficiency, alcoholism, age <4 years or elderly, pregnancy, less than one propylene glycol–containing drug
- Statins: Thiamine deficiency, hepatic insufficiency
- Topiramate: Dose-dependent, renal insufficiency

Respiratory acidosis

General risks

- Patients with sepsis or on a ventilator with fixed settings receiving enteral or parenteral nutrition

- Patients with underlying chronic respiratory acidosis (e.g., brainstem infarct, obesity-hypoventilation syndrome, tumors, poliomyelitis, multiple sclerosis, diaphragmatic paralysis, COPD, kyphoscoliosis, interstitial pulmonary disease)

Drug risks

- High doses of respiratory depressants (dose-related effect)
- Overdose of any agent with sedative properties
- Total calories delivered through enteral or parenteral solutions

CD4 = cluster of differentiation 4, COPD = chronic obstructive pulmonary disease, eGFR = estimated glomerular filtration rate, IV = intravenous, NRTI = nucleoside reverse-transcriptase inhibitor.

Table 44-6 Approaches to Help Prevent Drug-Induced Acidosis and Alkalosis

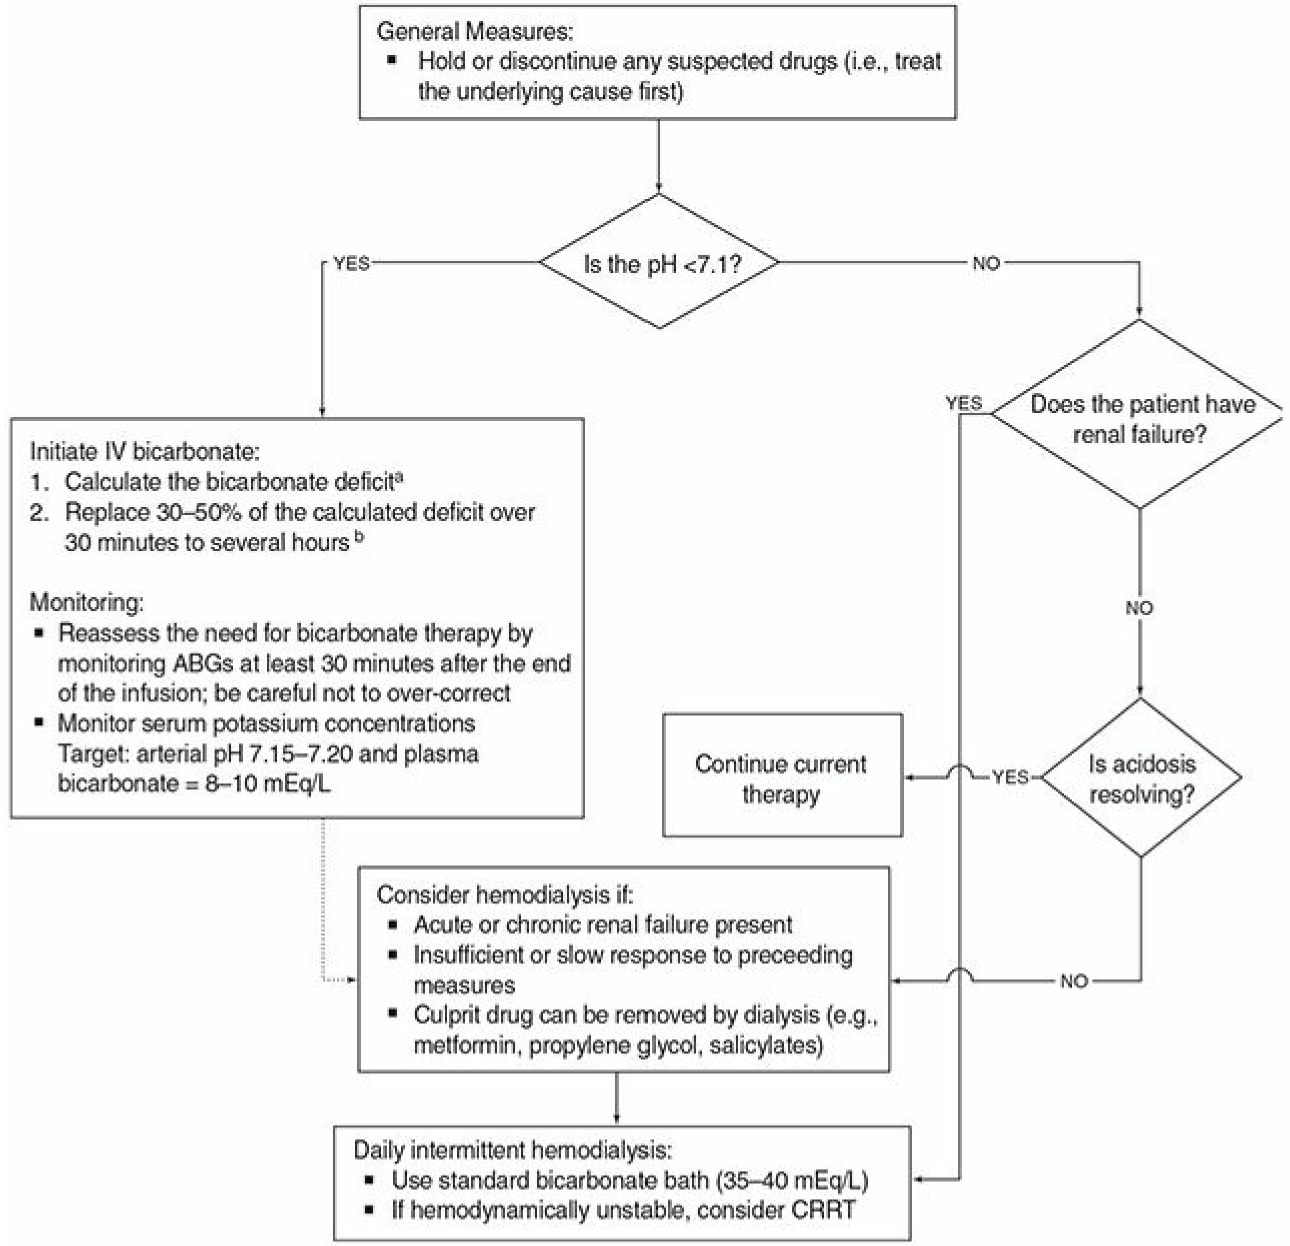
- Counsel about the early signs and symptoms of acidosis or alkalosis if the patient receiving a high-risk drug or has underlying risk factors
- Identify and minimize use of high-risk drugs
- Preventive monitoring using laboratory tests is not recommended

Table 44-7 Intravenous Medications Containing Propylene Glycol[42,95-97]

- Chlordiazepoxide
- Diazepam
- Digoxin
- Esmolol
- Etomidate
- Hydralazine
- Lorazepam
- Multivitamims
- Nitroglycerin
- Pentobarbital
- Phenobarbital
- Phenytoin
- Trimethoprim–sulfamethoxazole

MANAGEMENT

Treatment of drug-induced metabolic acidosis involves prompt identification and discontinuation of the offending agent. Other important aspects of treatment include ensuring adequate oxygen supply to tissues through proper ventilation and reducing oxygen demand by using sedation when indicated.[16] Intravenous bicarbonate therapy is reserved for more severe cases (i.e., pH <7.1) because this therapy carries the potential for fluid overload and hypernatremia and because the effect on plasma bicarbonate concentration may be only temporary.[16,17] Specific treatment measures are outlined in **Figure 44-1**. The goal of sodium bicarbonate therapy is to return the blood pH to a safer level (pH 7.15–7.2) or to increase the plasma bicarbonate to 8–10 mEq/L.



General Measures:
▪ Hold or discontinue any suspected drugs (i.e., treat the underlying cause first)
Is the pH <7.1?
YES
NO
Does the patient have renal failure?
YES
NO
Initiate IV bicarbonate:
1. Calculate the bicarbonate deficit[a]
2. Replace 30–50% of the calculated deficit over 30 minutes to several hours[b]
Monitoring:
▪ Reassess the need for bicarbonate therapy by monitoring ABGs at least 30 minutes after the end of the infusion; be careful not to over-correct
▪ Monitor serum potassium concentrations
Target: arterial pH 7.15–7.20 and plasma bicarbonate = 8–10 mEq/L
Continue current therapy
YES
Is acidosis resolving?
NO
Consider hemodialysis if:
▪ Acute or chronic renal failure present
▪ Insufficient or slow response to preceeding measures
▪ Culprit drug can be removed by dialysis (e.g., metformin, propylene glycol, salicylates)
Daily intermittent hemodialysis:
▪ Use standard bicarbonate bath (35–40 mEq/L)
▪ If hemodynamically unstable, consider CRRT

FIGURE 44-1 Treatment of Metabolic Acidosis (excluding RTA)

ABG = arterial blood gas, CRRT = continuous renal replacement therapy, RTA = renal tubular acidosis.

[a] Bicarbonate deficit (mEq) = 0.5 L/kg × weight (kg) × $[HCO_3]$ desired – $[HCO_3]$ observed, where 0.5 L/kg = volume of distribution of bicarbonate, HCO_3 = plasma bicarbonate concentration.

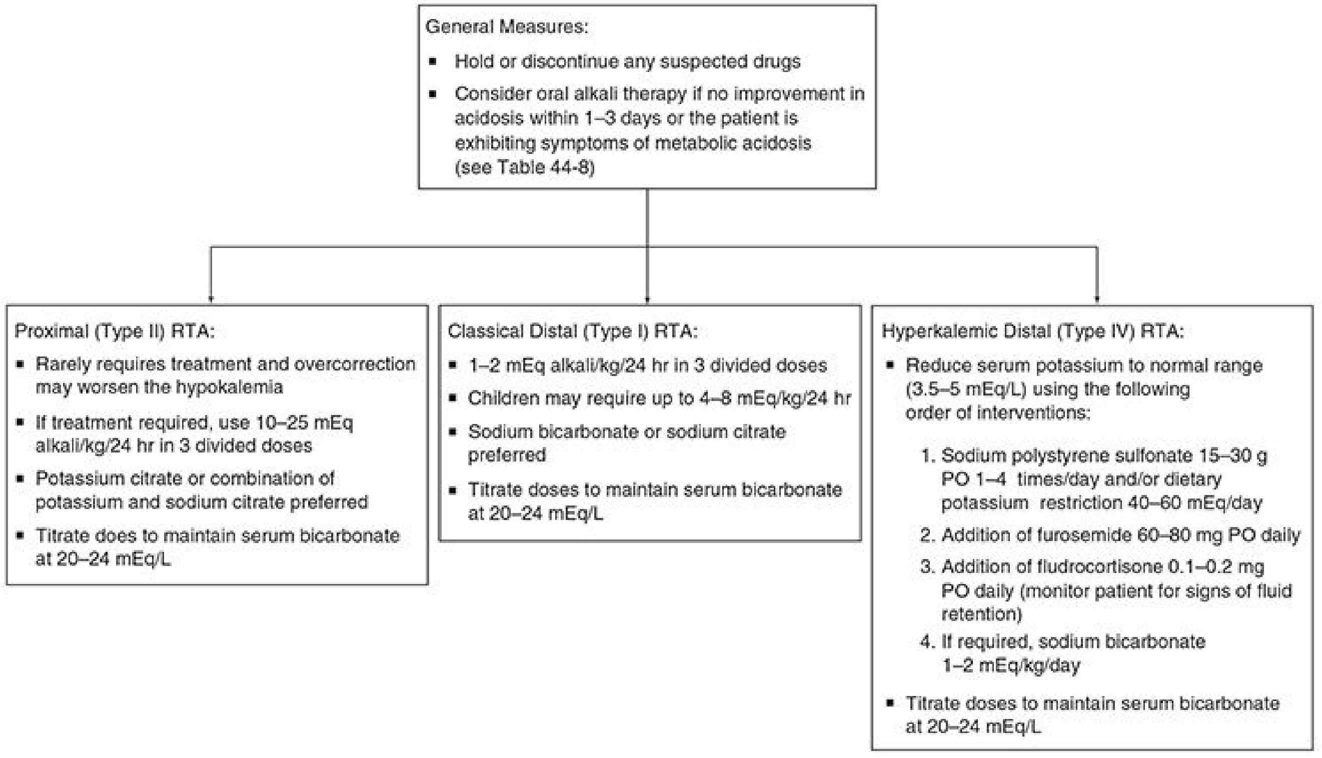
[b] Usual dose 100–150 mEq (2–3 ampules) $NaHCO_3$ in 0.9% NaCl, D5W, or other compatible fluid.

Source: Adroque HJ, Madias NE. Management of life-threatening acid-base disorders. *N Engl J Med.* 1998; 338:26-34.

Thiamine, riboflavin, and L-carnitine have been used to treat patients with NRTI-induced acidosis because these agents are necessary enzyme cofactors in the mitochondrial respiratory chain. Thiamine (100–200 mg daily), riboflavin (50 mg daily), and L-carnitine (1,000 mg twice daily) have been used together and individually (orally and intravenously) in the treatment of NRTI-induced lactic acidosis.[18,19] Current guidelines recommend changing to an NRTI-sparing regimen after patients completely recover from NRTI-induced lactic acidosis.[20]

Continuous or intermittent hemodialysis may be used in the treatment of metformin-, propylene glycol-, and propofol-induced metabolic acidosis to facilitate removal of metformin, propylene glycol, and the metabolic acids and lipids that accumulate with propofol infusion syndrome. Hemodialysis can also correct acidosis through bicarbonate supplementation and removal of lactate from the circulation.[21-23]

Drug-induced RTA is generally reversible upon discontinuation of the drug. If the acidosis does not improve within 1–3 days or the patient is symptomatic, oral alkali therapy may be considered. Treatment of proximal (Type II) RTA requires large doses of alkali because of the significant excretion of bicarbonate. Potassium citrate or combinations of potassium and sodium citrate are used, because low serum potassium concentrations due to distal potassium wasting are a consistent finding in proximal RTA. Classical distal (Type I) RTA responds to treatment with oral sodium bicarbonate. Reduction of serum potassium concentrations to within the normal range may reverse acidosis in patients with hyperkalemic (Type IV) distal RTA. **Table 44-8** lists the available options for oral alkali replacement therapy and **Figure 44-2** provides an algorithm for treatment of RTA.



General Measures:

- Hold or discontinue any suspected drugs
- Consider oral alkali therapy if no improvement in acidosis within 1–3 days or the patient is exhibiting symptoms of metabolic acidosis (see Table 44-8)

Proximal (Type II) RTA:

- Rarely requires treatment and overcorrection may worsen the hypokalemia
- If treatment required, use 10–25 mEq alkali/kg/24 hr in 3 divided doses
- Potassium citrate or combination of potassium and sodium citrate preferred
- Titrate does to maintain serum bicarbonate at 20–24 mEq/L

Classical Distal (Type I) RTA:

- 1–2 mEq alkali/kg/24 hr in 3 divided doses
- Children may require up to 4–8 mEq/kg/24 hr
- Sodium bicarbonate or sodium citrate preferred
- Titrate doses to maintain serum bicarbonate at 20–24 mEq/L

Hyperkalemic Distal (Type IV) RTA:

- Reduce serum potassium to normal range (3.5–5 mEq/L) using the following order of interventions:
  1. Sodium polystyrene sulfonate 15–30 g PO 1–4 times/day and/or dietary potassium restriction 40–60 mEq/day
  2. Addition of furosemide 60–80 mg PO daily
  3. Addition of fludrocortisone 0.1–0.2 mg PO daily (monitor patient for signs of fluid retention)
  4. If required, sodium bicarbonate 1–2 mEq/kg/day
- Titrate doses to maintain serum bicarbonate at 20–24 mEq/L

FIGURE 44-2 Treatment of Renal Tubular Acidosis

Table 44-8 Oral Alkali Replacement Products

Generic Name	Brand Name	mEq Bicarbonate
Potassium bicarbonate–potassium citrate	K-lyte	25 mEq bicarbonate/tablet (25 mEq K/tablet)
	K-lyte DS	50 mEq bicarbonate/tablet (50 mEq K/tablet)
Potassium citrate	Urocit-K	5 mEq, 10 mEq, or 15 mEq bicarbonate/tablet (5 mEq, 10 mEq, 15 mEq K/tablet)
Potassium citrate–citric acid	Polycitra K	2 mEq bicarbonate/mL (2 mEq K/mL)
Sodium bicarbonate	Various	325 mg tablet = 3.9 mEq bicarbonate (3.9 mEq Na) 650 mg tablet = 7.8 mEq bicarbonate (7.8 mEq Na)
Sodium citrate–citric acid	Shohl's solution, Bicitra	1 mEq bicarbonate/mL (1 mEq Na/mL)
Sodium citrate–potassium citrate–citric acid	Polycitra	2 mEq bicarbonate/mL (1 mEq K/mL and 1 mEq Na/mL)

K = potassium, Na = sodium.

The immediate restoration of normal alveolar gas exchange is the most important feature in the treatment of acute respiratory acidosis. Table 44-9 reviews treatment options for drug-induced acute respiratory acidosis. Successful management of chronic respiratory acidosis relies on the prompt recognition and treatment of the underlying conditions, such as for COPD or sepsis. Bicarbonate administration is rarely necessary, and rapid correction of respiratory acidosis with bicarbonate may eliminate the patient's respiratory drive or precipitate an acute metabolic alkalosis.[1] Sodium bicarbonate infusions used to treat respiratory acidosis can buffer hydrogen ions; however, dissociation can also lead to unwanted formation of CO_2. The effects of sodium bicarbonate overall on correcting the pH then become dependent on the patient's ability to eliminate that CO_2. Tracheal intubation with mechanical ventilation is key at this point and should continue until the underlying cause of acidosis is resolved. In addition to the extracellular effects of bicarbonate administration, generated CO_2 passively diffuses into cells where carbonic acid is formed. This can worsen intracellular acidosis.[24] Tris-hydroxymethyl aminomethane (THAM) may be considered as an alternative to bicarbonate administration because it buffers respiratory acidosis and, unlike bicarbonate, easily enters cells to buffer pH and reduce CO_2 levels. THAM may more effectively correct pH and mitigate adverse effects of the acidosis in patients with severe cardiovascular and hemodynamic instability.[24]

Table 44-9 Treatment Options for the Management of Acute Drug-Induced Respiratory Acidosis

- Hold or discontinue any respiratory depressant drugs
- Reverse effects of respiratory depressants, if present:
    - For opiates: Give naloxone 0.04–0.4 mg IV/IM. Sub-Q may provide more gradual reversal than IV. Naloxone may be administered via nebulization or by endotracheal tube. Response should be observed within 1–2 minutes after IV dose; duration of naloxone action is variable from 0.5–3 hours; and repeated administration may be required. Naloxone may also be administered as a continuous IV infusion (0.4–0.8 mg/hr in 5% dextrose). Guidelines recommend using the lowest effective dose of naloxone to prevent respiratory acidosis and minimize the risk of withdrawal in opiate-dependent patients.[98,122]
    - For benzodiazepines: give flumazenil 0.2 mg IV q 1 min as needed (maximum, 5 doses per series; may repeat series at 20-minute intervals up to 5-mg total dose); obtain arterial blood gases every 2–4 hours initially then every 12–24 hours as acidosis improves; flumazenil is not recommended in the absence of specific knowledge of a benzodiazepine overdose as its administration may precipitate seizures in patients with tricyclic antidepressant overdose[98]

IM = intramuscular, IV = intravenous, sub-Q = subcutaneous.

INFORMATION FOR PATIENTS

Patients receiving drugs known to cause acidosis should be aware that associated symptoms are not specific and may include epigastric pain, nausea, vomiting, lethargy, somnolence, and diarrhea. Many patients who have experienced NRTI-induced lactic acidosis describe a 2- to 4-week prodrome that has included nausea, vomiting, weight loss, and abdominal pain and distention.[10] The occurrence of any of these symptoms should be reported to a healthcare provider.

Patients receiving large doses of central respiratory depressants and their caregivers should be cautioned to be alert to the signs and symptoms of respiratory acidosis, including altered mental status and abnormal behavior.

ALKALOSIS

CAUSATIVE AGENTS

Metabolic alkalosis is a primary increase in serum bicarbonate concentration and occurs as a consequence of a loss of hydrogen ions or/and a gain in bicarbonate. Patients with metabolic alkalosis present with an elevated arterial pH, increased plasma bicarbonate concentration, and a compensatory decrease in lung ventilation (hypoventilation) resulting in an increased partial pressure of CO_2. Hypochloremia and/or hypokalemia may also be present.[8] Because the kidney under normal circumstances is able to excrete a significant alkali load, evaluation of patients with metabolic alkalosis must include both an assessment of the process initially responsible for the acid–base abnormality as well as the alterations in renal function that are preventing prompt correction of the alkalemic state.

Respiratory alkalosis is a condition of elevated arterial pH and hyperventilation resulting in a low partial pressure of CO_2 with a compensatory decrease in plasma bicarbonate concentration. Similar to respiratory acidosis, respiratory alkalosis can be classified as acute or chronic depending on the degree of bicarbonate compensation observed. Drugs reported to cause metabolic or respiratory alkalosis are listed in **Table 44-10**.

EPIDEMIOLOGY

Metabolic alkalosis is a common acid–base disorder, accounting for a large proportion of all acid–base disorders.[25] The high incidence is attributed to the frequency of vomiting and the use of diuretics and nasogastric suction in hospitalized patients. Respiratory alkalosis is the most common acid–base abnormality observed in critically ill patients because it is associated with numerous illnesses and is a common finding in patients on mechanical ventilation.[8] However, the incidence of drug-induced respiratory alkalosis is not well defined.

MECHANISMS

Table 44-11 lists the mechanisms of metabolic and respiratory drug-induced alkalosis. The development and continuation of metabolic alkalosis requires both an elevation in the plasma bicarbonate concentration and a decrease in renal bicarbonate excretion. There are three major mechanisms of metabolic alkalosis. The first involves extracellular fluid (ECF) volume contraction, low blood pressure, potassium deficiency, and secondary hyperaldosteronism. ECF volume contraction leads to an increased plasma bicarbonate concentration, whereas low blood pressure decreases glomerular filtration rate in the kidneys, leading to decreased renal bicarbonate excretion. Secondary hyperaldosteronism occurs and is an attempt to correct the volume contraction and low blood pressure, and hypokalemia is the result of aldosterone's effect on potassium excretion. Hyperaldosteronism and hypokalemia both directly increase renal bicarbonate reabsorption and lead to an increased plasma bicarbonate concentration. Treatment with diuretics may produce hypochloremia, which reduces bicarbonate excretion by increasing renal distal tubule reabsorption and reducing renal distal tubule secretion of bicarbonate. It has been suggested that this type of metabolic alkalosis would more accurately be termed *chloride depletion alkalosis.* Animal models and a study in healthy human volunteers found that metabolic alkalosis can be corrected with chloride repletion alone (without volume expansion), whereas volume expansion without chloride administration does not correct the alkalosis.[26] When volume deficits exist in patients with alkalosis, they are typically corrected with solutions of 0.9% sodium chloride.

The second major mechanism of metabolic alkalosis involves ECF volume expansion, hypertension, hypokalemia, and mineralocorticoid excess. Drugs with mineralocorticoid activity produce aldosterone-like effects. The resulting increased absorption of sodium and water leads to ECF volume expansion and hypertension, and the increased potassium excretion leads to hypokalemia. The net result is that aldosterone-like effects and hypokalemia increase bicarbonate reabsorption and lead to the development of metabolic alkalosis.

Table 44-10 Agents Implicated in Drug-Induced Alkalosis

Drug	Incidence	Level of Evidence[a]
METABOLIC ALKALOSIS		
Acetate[98]	NK	C
Anions—nonreabsorbable, large doses (Penicillins,[99,100] Carbapenems)[101,102]	NK	C
Aminoglycosides[103-106]	NK	C
Calcium carbonate (calcium-alkali syndrome, reported with doses 4–60 g/day, may occur with lower doses)[35,36]	NK	C
	NK	C

Cisplatin[107]		
Citrate (from transfused blood, fresh-frozen plasma, or citrate anticoagulation in continuous renal replacement therapies)	NK	C
Diuretics (loop and thiazide)[108,109]	NK	B
Fludrocortisone[110]	NK	C
Glycyrrhizic acid (found in genuine black licorice, chewing tobacco, herbal products containing licorice)[37,111]	NK	C
Laxative abuse[77]	NK	B
Sodium bicarbonate—excessive administration (found in nonprescription antacids, IV sodium bicarbonate, baking soda)[38,112-115]	NK	B
Sodium polystyrene sulfonate combined with aluminum or magnesium hydroxide[116,117]	NK	C
Stanozolol[118]	NK	C
RESPIRATORY ALKALOSIS		
Amphetamines	NK	C
Catecholamines[91]	NK	C
Doxapram[28,29,118]	NK	A
Loratadine (overdose)[121]	NK	C
Nicotine	NK	C
Progesterone[119]	NK	A
Quetiapine[30]	NK	C
Salicylate (overdose—mixed disorder: metabolic acidosis and respiratory alkalosis)[68]	NK	B
Theophylline (overdose)[120]	NK	B

IV = intravenous, NK = not known.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

The third major mechanism involves exogenous alkali loading. Sustained metabolic alkalosis usually occurs in patients who have underlying risk factors (e.g., renal dysfunction) and receive large doses of alkali-containing drugs such as antacids, sodium bicarbonate (e.g., baking soda), or bicarbonate precursors (citrate, acetate).

Drug-induced respiratory alkalosis occurs as a result of stimulation of the central respiratory center and the subsequent increase in minute ventilation and reduction in the partial pressure of CO_2. Progesterone exerts this effect and rising endogenous progesterone concentrations may in fact be responsible for inducing respiratory alkalosis in pregnant women. Medroxyprogesterone has been shown to induce small but sustained decreases in the partial pressure of CO_2 and increases in serum bicarbonate concentrations and has been used to treat patients with central hypoventilation.[27] Doxapram increases respiratory rate and can cause respiratory alkalosis. It has been used for patients in intensive care units to help obviate the need for intubation and mechanical ventilation, although its use is limited by its propensity to induce cardiac arrhythmia.[28,29] Quetiapine has been associated with hyperventilation and respiratory alkalosis possibly secondary to peripheral serotonin depletion.[30] Serotonin is known to be involved in the regulation of ventilation. It has been hypothesized that hyperventilation results from serotonin depletion at vagal receptor sites in the airway and lungs.[30]

Table 44-11 Mechanisms of Drug-Induced Alkalosis

Drug	Mechanism
METABOLIC ALKALOSIS	
Aminoglycosides	Bartter-like syndrome
Cisplatin Large doses of nonreabsorbable anion Loop and thiazide diuretics	ECF volume contraction (renal origin), normotension, hypokalemia, and secondary hyperaldosteronism
Combined administration of sodium polystyrene sulfonate and aluminum or magnesium hydroxide Laxative abuse	ECF volume contraction (gastrointestinal origin), normotension, hypokalemia, and secondary hyperaldosteronism
Fludrocortisone Glycyrrhizic acid (found in genuine black licorice, chewing tobacco, herbal products containing licorice) Stanozolol	ECF volume expansion, hypertension, hypokalemia, and mineralocorticoid excess
Acetate Calcium carbonate (calcium-alkali syndrome) Citrate (from transfused blood, fresh-frozen plasma, or citrate anticoagulation in renal replacement therapies) Excessive sodium bicarbonate injection/administration (found in over-the-counter antacids, intravenous sodium bicarbonate, baking soda)	Exogenous alkali load
RESPIRATORY ALKALOSIS	
Amphetamines	Central respiratory stimulation

Doxapram	Central respiratory stimulation
Loratadine overdose	Central respiratory stimulation
Progesterone	Central respiratory stimulation
Quetiapine	Hyperventilation secondary to peripheral serotonin depletion
Salicylate overdose (mixed disorder: metabolic acidosis and respiratory alkalosis)	Central respiratory stimulation
Theophylline overdose	Central respiratory stimulation

ECF = extracellular fluid.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Mild-to-moderate metabolic alkalosis, with serum bicarbonate levels <40 mEq/L, is usually asymptomatic. Often it is the electrolyte abnormalities, such as hypokalemia, that lead to signs and symptoms such as paresthesias, muscle cramping, tetany, and cardiac arrhythmias. When serum bicarbonate levels exceed 45 mEq/L, hypoxemia secondary to compensatory hypoventilation may occur, especially in patients with COPD. Mental status changes, seizures, and coma may occur with serum bicarbonate levels >50 mEq/L.[31]

The cause of metabolic alkalosis can often easily be discerned with careful medical and medication histories and physical examination. However, without arterial blood gas measurements, metabolic alkalosis may be difficult to distinguish from respiratory acidosis, as the signs and symptoms are similar (Table 44-3 and **Table 44-12**). Patients presenting with metabolic alkalosis associated with ECF volume contraction may exhibit orthostatic hypotension, tachycardia, and other features of reduced circulatory volume. Unless they are receiving diuretic therapy and have associated chloride depletion, these patients generally have intense chloride conservation, with urinary concentrations <10 mEq/L. In metabolic alkalosis associated with ECF volume expansion and mineralocorticoid excess, patients tend to present with hypertension and urinary chloride concentrations >30 mEq/L. Urine chloride concentrations between 10 and 30 mEq/L are associated with various causes such as severe hypokalemia, diuretic-induced volume depletion, Bartter and Gitelman syndromes, or alkali ingestion. Therefore, results within this range are not helpful in determining the cause of metabolic alkalosis.[31] Urinary potassium concentrations >30 mEq/L in the presence of hypokalemia indicate renal potassium wasting, often from diuretic therapies.[32] Conditions to consider in the differential diagnosis of metabolic alkalosis are listed in **Table 44-13**.

Table 44-12 Signs and Symptoms Associated with Alkalosis[98]

Signs and symptoms
MILD TO MODERATE METABOLIC ALKALOSIS (pH 7.5–7.6)
• Extracellular fluid volume depletion and postural hypotension
• Hypokalemia
• Muscle weakness
SEVERE METABOLIC ALKALOSIS (pH >7.6)
• Cardiac arrhythmias
• Confusion
• Hyperactive reflexes or tetany
• Hypoxemia stimulated tachypnea
• Muscle cramping
• Paresthesia
RESPIRATORY ALKALOSIS
• Arrhythmias
• Confusion
• Neuromuscular irritability
• Seizures
• Decreased cardiac output
• Dizziness
• Ischemic ECG changes
• Hyponatremia
• Hypokalemia
• Hyperchloremia
o Hyponatremia
o Hypokalemia
o Hyperchloremia

ECG = electrocardiogram.

The clinical features of respiratory alkalosis are listed in Table 44-12. In addition to a physical examination and medication history, the diagnostic workup should include arterial blood gases to avoid possible misdiagnosis as metabolic acidosis. Conditions to consider in the differential diagnosis of drug-induced respiratory alkalosis are listed in Table 44-13.

RISK FACTORS

Patients with underlying medical causes of hydrochloric acid loss, such as vomiting or nasogastric suction, or reduced renal bicarbonate excretion due to low effective blood volume may be at higher risk of experiencing drug-induced metabolic alkalosis. Patients with renal dysfunction are more likely to develop metabolic alkalosis with large doses of alkali-containing drugs. With primary respiratory alkalosis, the elevation in pH and decrease in pCO_2 occur as the result of any disorder that increases respiratory drive. Risk factors for metabolic and respiratory alkalosis are presented in **Table 44-14**.

MORBIDITY AND MORTALITY

Although specific rates of morbidity and mortality for patients with drug-induced alkalosis are not known, mortality rates for alkalosis of all types have been published. Patients with arterial blood pH of 7.55 have been found to have a mortality rate of 45% and mortality increases to 80% when pH is >7.65.[33] Hospitalized patients with respiratory alkalosis and a partial pressure of arterial CO_2 <15 mm Hg have a mortality rate of approximately 90%.[34]

Table 44-13 Conditions to Consider in the Differential Diagnosis of Drug-Induced Alkalosis[8,31,91]

Metabolic alkalosis

Exogenous bicarbonate administration

- Alkali administration
- Milk-alkali syndrome

ECF volume contraction, hypokalemia, and secondary hyperaldosteronism

- Gastrointestinal losses
  - Congenital chloridorrhea
  - High-volume ileostomy losses
  - Nasogastric suction
  - Villous adenoma
  - Vomiting
- Renal losses
  - Bartter syndrome (inherited defect in TALH characterized by alkalosis, hypokalemia, and normal-to-low blood pressure)
  - Gitelman syndrome (loss of function mutation in Na^+–Cl^- cotransporter in DCT)
  - Hypercalcemia/hypoparathyroidism
  - Hypokalemia
  - Magnesium deficiency
  - Posthypercapnic state
  - Recovery from lactic acidosis or ketoacidosis

ECF volume expansion, hypertension, hypokalemia, and mineralocorticoid excess

- Secondary hyperaldosteronism (high renin)
  - Accelerated hypertension
  - Renal artery stenosis
  - Renin-secreting tumor
- Low renin
  - Cushing syndrome or disease
  - Primary aldosteronism
  - Adrenal enzyme defects

    –11β-hydroxylase deficiency
    –17α-hydroxylase deficiency
- Liddle syndrome—Genetic disorder associated with increased function of renal sodium channel resulting in ECFV expansion, hypertension, K^+ deficiency, and hyporeninemic-hypoaldosteronism

Respiratory alkalosis

Central nervous system stimulation

- Anxiety-hyperventilation syndrome
- Cerebrovascular accident
- Fever
- Meningoencephalitis
- Pain
- Psychosis
- Trauma
- Tumor

Hypoxemia or tissue hypoxia

- Aspiration
- High altitude
- Pneumonia
- Pulmonary edema
- Severe anemia

Stimulation of chest wall receptors

- Acute respiratory distress syndrome
- Asthma
- Cardiac failure
- Flail chest
- Hemothorax
- Pneumonia
- Pneumothorax
- Pulmonary embolism

Miscellaneous

- Heat exposure
- Hepatic failure
- Mechanical hyperventilation
- Pregnancy (progesterone)
- Recovery from metabolic acidosis
- Septicemia

DCT = distal convoluted tubule, ECFV = extracellular fluid volume, TALH = thick ascending limb of Henle's loop.

MANAGEMENT

There are two goals in the treatment of metabolic alkalosis: (1) correct the existing deficit, and (2) prevent continuing bicarbonate gains by discontinuing the causative agent. Metabolic alkalosis associated with ECF volume contraction can be effectively treated with an infusion of 0.9% sodium chloride. This will correct both the volume and the chloride deficits. Patients with overt signs of volume contraction usually require a minimum of 3–5 L. As the chloride deficit is corrected, an alkaline diuresis will occur, with plasma bicarbonate decreasing toward normal.[32] Other treatment measures are outlined in **Figure 44-3**.

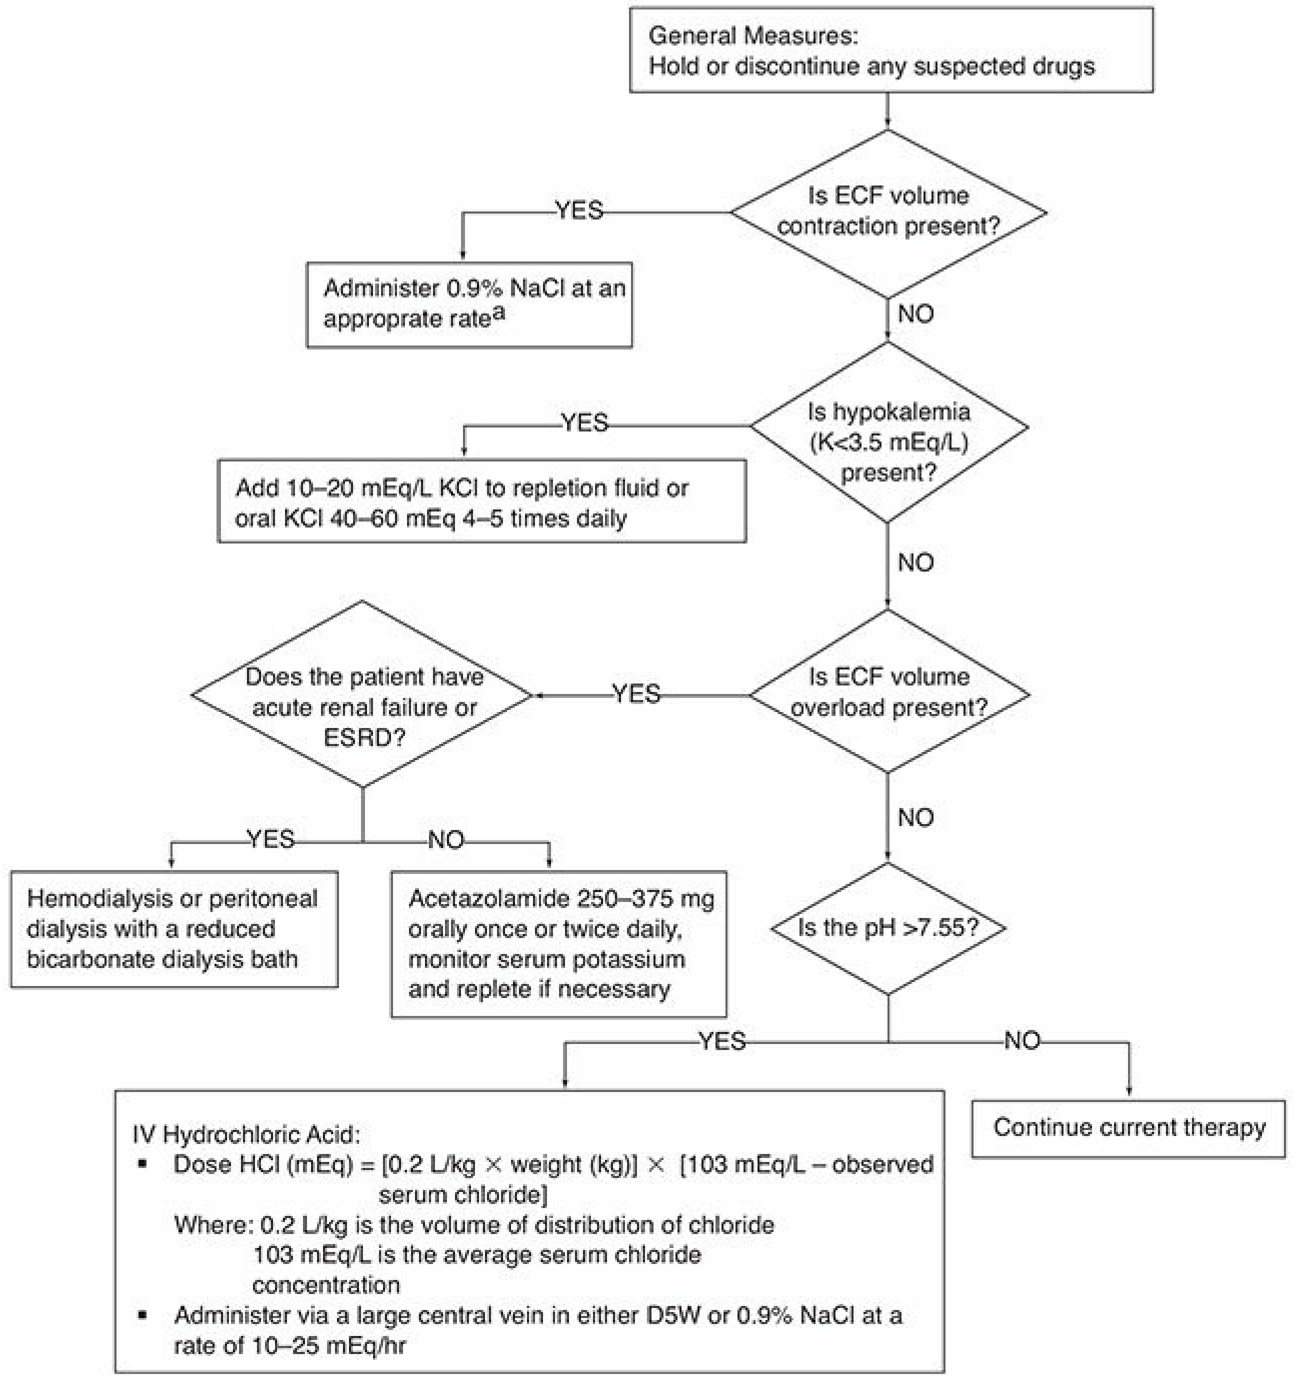
Table 44-14 Risk Factors for Drug-Induced Alkalosis[1,8]

Metabolic alkalosis

- Hemodynamic disturbances that impair bicarbonate excretion
- Renal dysfunction
- Vomiting or nasogastric suction

Respiratory alkalosis

- Altitude
- Anxiety
- Asthma
- Brain tumors, vascular accidents
- Carbon monoxide intoxication
- Fever
- Gram-negative sepsis
- Head trauma
- Heart failure
- Hepatic cirrhosis
- Hyperventilation (mechanical or voluntary)
- Hypotension
- Pain
- Pneumonia
- Pregnancy
- Pulmonary emboli
- Pulmonary shunts



General Measures:
Hold or discontinue any suspected drugs
Is ECF volume contraction present?
YES
Administer 0.9% NaCl at an approprate rate[a]
NO
Is hypokalemia (K<3.5 mEq/L) present?
YES
Add 10–20 mEq/L KCl to repletion fluid or oral KCl 40–60 mEq 4–5 times daily
NO
Is ECF volume overload present?
YES
Does the patient have acute renal failure or ESRD?
YES
NO
Hemodialysis or peritoneal dialysis with a reduced bicarbonate dialysis bath
Acetazolamide 250–375 mg orally once or twice daily, monitor serum potassium and replete if necessary
NO
Is the pH >7.55?
YES
NO
IV Hydrochloric Acid:
▪ Dose HCl (mEq) = [0.2 L/kg × weight (kg)] × [103 mEq/L – observed serum chloride]
Where: 0.2 L/kg is the volume of distribution of chloride
103 mEq/L is the average serum chloride concentration
▪ Administer via a large central vein in either D5W or 0.9% NaCl at a rate of 10–25 mEq/hr
Continue current therapy

FIGURE 44-3 Treatment of Metabolic Alkalosis

ECF = extracellular fluid, ESRD = end-stage renal disease, HCl = hydrochloric acid, KCl = potassium chloride, NaCl = sodium chloride.

[a] For severe dehydration, administer 1 L 0.9% NaCl over 30 minutes followed by a second liter over the next hour. Repeat physical examination and electrolytes to determine subsequent rate of administration.

The only effective therapy in patients with respiratory alkalosis is elimination of the underlying cause of hyperventilation. If a medication is suspected, its use should be discontinued. Management of salicylate and theophylline overdose includes supportive care and administration of activated charcoal to reduce absorption. Intravenous sodium bicarbonate is used to alkalinize the urine and to enhance urinary excretion of salicylates. Whole bowel irrigation may be used to enhance elimination of sustained-release theophylline. Hemodialysis or hemoperfusion is recommended to enhance elimination in severe cases of salicylate or theophylline overdose. Oxygen therapy should be initiated in all patients with severe hypoxemia (partial pressure of oxygen <40 mm Hg), and patients with life-threatening alkalosis (pH >7.6) may require mechanical ventilation to control hyperventilation.[1] **Table 44-15** summarizes the treatment options available for drug-induced respiratory alkalosis.

INFORMATION FOR PATIENTS

Patients exposed to drugs that can induce metabolic alkalosis should be instructed to report muscle weakness or cramping (hypokalemia), tetany (hypocalcemia), or postural dizziness (ECF volume depletion) promptly to their healthcare provider. To avoid development of calcium-alkali syndrome in patients with risk factors for metabolic alkalosis, intake of calcium supplements should be limited to no more than 1.2–1.5 g per day of elemental calcium (includes total from diet and supplements). This is especially important in patients exposed to other sources of alkali or when there is concomitant use of agents associated with drug-induced alkalosis.[35,36] An indication of possible diuretic or laxative abuse may be identified by clinicians during a review of a patient's purchase or refill history, and these patients should be cautioned regarding the risks associated with this practice. Patients should also be warned about the use of herbal supplements with mineralocorticoid activity (e.g., natural licorice) and overuse of baking soda as a home remedy.[37,38]

Patients should be advised to take medications known to cause respiratory alkalosis exactly as directed to prevent unintentional overdose. Patients receiving large doses of aspirin for treatment of arthritis or other conditions should be made aware of, and advised to avoid, other salicylate-containing medications to prevent accidental overdose. Patients should also be instructed to promptly report symptoms of light-headedness, confusion, syncope, or seizures to their healthcare provider.

Table 44-15 Treatment Options for Management of Drug-Induced Respiratory Alkalosis[98]

- Hold or discontinue any suspected drugs
- Initiate oxygen therapy in patients with severe hypoxemia (partial pressure of oxygen <40 mm Hg)
- Rebreathing techniques are effective in patients with hyperventilation due to anxiety
- Treat theophylline and salicylate overdoses appropriately

Bleeding Disorders

Tiffany Pon and Jaekyu Shin

Drug-induced bleeding is a common problem. In this chapter, we use the term *drug-induced* to describe situations in which drugs cause, exacerbate, or increase the risk of bleeding. As anticoagulant and antiplatelet therapies have become the mainstay of treatment for various cardiovascular diseases, the utilization of drugs that increase bleeding risk has grown. From 1995 to 2002, the percentage of patients with atrial fibrillation who received an anticoagulant increased from 40.3% to 49.1%.[1] Furthermore, patients may take multiple drugs that increase bleeding risk, and polypharmacy greatly increases the risk of drug-induced bleeding as many agents are prone to drug–drug interactions and have narrow therapeutic indices. Drug-induced bleeding events not only lead to morbidity and mortality but they are also costly. In one study, mean unadjusted all-cause health costs in the first year after warfarin initiation for atrial fibrillation was approximately $42,000 for patients with at least one intracranial bleed compared with $24,000 for patients without bleeding.[2] As a result, many of the drugs discussed in this chapter are considered high-alert medications by the Institute for Safe Medication Practices, and clinicians should be aware of how to prevent, recognize, and manage drug-induced bleeding.

CAUSATIVE AGENTS

Drugs associated with bleeding can be divided primarily into two groups: those that affect hemostasis through inhibition of the coagulation cascade and platelet aggregation pathways and those that exert direct toxicity (**Table 45-1**).[3-152]

Drugs that impair hemostasis include anticoagulants, thrombolytics, and antiplatelet agents, and they are intended to treat or prevent thrombosis. Thus, while they do not directly cause bleeding, they can exacerbate or increase the risk of bleeding from other causes. In contrast, nonsteroidal anti-inflammatory drugs (NSAIDs) primarily increase bleeding risk by inhibiting prostaglandin synthesis in the upper gastrointestinal mucosa, causing direct damage.[153]

Aspirin falls into both groups because it exerts similar direct gastrointestinal toxicity as NSAIDs, but it also affects hemostasis through inhibition of platelet aggregation.[154] Finally, selective serotonin reuptake inhibitors (SSRIs) are thought to increase bleeding risk through inhibition of platelet aggregation; however, there is also evidence that they may directly increase gastric acidity, which increases the risk of ulceration and gastrointestinal bleeding.[155,156]

EPIDEMIOLOGY

The incidence of drug-induced bleeding has been reported in multiple randomized clinical trials, and risk differs by drug class (Table 45-1). The site of bleeding is often also a function of drug class. Vitamin K antagonists (VKAs) are more likely to cause intracranial hemorrhage (ICH) than direct oral anticoagulants (DOACs), whereas DOACs are more likely to cause gastrointestinal bleeding than VKAs, and upper gastrointestinal bleeding is highly associated with aspirin and NSAIDs.[6,9,11,12,90,130,131] Moreover, drug-induced bleeding may differ by ethnicity, with Caucasians possibly having a lower risk of drug-induced bleeding.[157-159]

Table 45-1 Agents Implicated in Drug-Induced Bleeding

Drug	Incidence	Level of Evidence[a]
ANTICOAGULANTS		
Direct oral thrombin inhibitors[10,11,37-40]	9.7–16.1% (all[b]); 0.–1.4% (major[c])	A
Direct oral Xa inhibitors[6,9,12-28]	4.9–21.7% (all); <0.1%–0.8% (major)	A
Fondaparinux[29-36]	1.0–5.3% (all); 0.1–2.2% (major)	A
IV direct thrombin inhibitors[41-59]	3.2–12.5% (all); 0–13.8 (major)	A, B

Low-molecular-weight heparin[5,7,25,27,28,32-35,58,60-80]	0.6–25.4% (all); 0–9.1% (major)	A
Unfractionated heparin[31,32,36,65,69-75,77,78,80,81]	2.1–18.4% (all); 0.1–8.3% (major)	A
Vitamin K antagonists[3-12]	13.2–25.8%/yr (all); 2.2–3.43% (major)	A
ANTIPLATELET DRUGS		
Anagrelide[128,129]	11.3–18.9% (all); 4.1% (major)	A, B
Aspirin[62,82-90]	1.8–16.1% (all);1.3%/yr–3.9% (major)	A
Aspirin plus dipyridamole[88,89,91]	1.19%/yr; 0.09%/yr–4.1% (major)	A
Cilostazole[122-125]	0.7–4% (all); 0% (major)	A
Dipyridamole[88-89]	15.1% (all); 2.6% (major)	A
GPIIb/IIIa inhibitors[106-121]	3–23.5% (all); 0.2–10.6% (major)	A
IV P2Y12 receptor antagonists[102-105]	0.3–11.8% (all); 0.1–0.4% (major)	A
Oral P2Y12 receptor antagonists[84-87,89,92-101]	0.1–11.4% (all); 0.1–7.9% (major)	A
OTHER AGENTS		
Defibrotide[150,d]	1% (all)	A
NSAIDs[130-134]	6.0% (all); 0.4–4.9% (GI bleed)	A, B
SSRIs[151,152]	0.4–0.6% (GI bleed)	B
Thrombolytics[135-149]	20.3–32% (all); 2.7–10% (major)	A
Vorapaxar[126,127,e]	2.8–3.2 (major)	A

GI = gastrointestinal, GPIIb/IIIa inhibitors = glycoprotein IIb/IIIa inhibitors, IV = intravenous, NSAID = nonsteroidal anti-inflammatory drug, SSRI = selective serotonin reuptake inhibitor.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] All-cause bleeding.

[c] Major bleeding.

[d] Incidences of major bleeding were not reported.

[e] Incidences of all-cause bleeding were not reported.

The true incidence of drug-induced bleeding, however, is not completely clear because it is impacted by several factors. Some factors relate to study design (e.g., inconsistent bleeding classifications and definitions, varying study durations, and different statistical methods), and other factors include concomitant medication use and continuously evolving practice standards.

Classifications of bleeding have included major, fatal, life-threatening, serious, excessive, clinically significant, overt, trivial, minor, nuisance bleeding events, and more, and the definitions of these classifications have also differed among trials. Criteria used in selected clinical trials involving nonsurgical patients are listed in **Table 45-2**.

Table 45-2 Bleeding Definitions

Criteria	Bleeding Definition
Thrombolysis in Myocardial Infarction (TIMI)[160]	• Major: o Any intracranial bleeding (excluding hemorrhages <10 mm evident only on gradient-echo magnetic resonance imaging scan) o Clinically overt signs of hemorrhage associated with a drop in hemoglobin of ≥ 5 g/dL o Fatal bleeding (bleeding that directly results in death within 7 days) • Minor: Clinically overt, resulting in hemoglobin drop of 3–5 g/dL • Requiring medical attention: Any overt sign of hemorrhage that meets one of the following criteria and does not meet criteria for a major or minor bleeding event, as defined above: o Requiring intervention (medical practitioner-guided medical or surgical treatment to stop or treat bleeding, including temporarily or permanently discontinuing or changing the dose of a medication or study drug) o Leading to or prolonging hospitalization o Prompting evaluation (leading to an unscheduled visit to a healthcare professional and diagnostic testing, either laboratory or imaging)
Global Use of Strategies to Open Occluded Arteries (GUSTO)[160]	• Severe or life-threatening bleeding: o Intracerebral hemorrhage o Resulting in substantial hemodynamic compromise requiring treatment • Moderate: Requiring blood transfusion but not resulting in hemodynamic compromise • Mild: Bleeding that does not meet above criteria
International Society on Thrombosis and Haemostasis (ISTH)[161,162]	• Major bleeding: o Fatal bleeding, and/or o Symptomatic bleeding in a critical area or organ, such as intracranial, intraspinal, intraocular, retroperitoneal, intraarticular or pericardial, or intramuscular with compartment syndrome, and/or o Bleeding causing a fall in hemoglobin level of 2 g/dL or more, or leading to transfusion of two or more units of whole blood or red cells • Clinically relevant nonmajor bleeding: o Any sign or symptom of hemorrhage (e.g., more bleeding than would be expected for a clinical circumstance, including bleeding found by imaging alone) that does not fit the criteria for the ISTH definition of major bleeding but does meet at least one of the following criteria: • Requiring medical intervention by a healthcare professional • Leading to hospitalization or increased level of care • Prompting a face-to-face (i.e., not just a telephone or electronic communication) evaluation

Clinical trials of longer duration typically report a higher incidence of bleeding compared to trials of shorter duration, and this may be due to the use of different methods to calculate the incidence of bleeding events. Although percent incidence is most commonly used to describe risk, percent per year and incidence rates such as person-years have also been used.

Concomitant use of multiple medications that can induce or exacerbate bleeding also confounds determination of the true incidence of bleeding for each individual drug. Virtually all trials evaluating clopidogrel in acute coronary syndrome included patients who also took aspirin, and patients who were assigned to a glycoprotein (GP) IIb/IIIa inhibitor often received unfractionated heparin (UFH) at the same time.

In addition to combination therapy, clinical trial protocols may not represent current clinical practice, and this can also confound determination of true bleeding incidence. The majority of trials testing GPIIb/IIIa inhibitors, for example, did not use a P2Y12 antagonist during percutaneous coronary intervention (PCI) despite this being a current standard of practice, and many venous thromboembolism (VTE) trials assessing UFH used a different dose than that used currently in most practices.[77,78,163] As a result, it is difficult to compare the incidence of bleeding events between the trials.

MECHANISMS

The coagulation cascade pathway involves a series of serine proteases leading to the eventual generation of fibrin (**Figure 45-1**). The platelet aggregation pathway provides platelet plugs via the following events: adhesion of platelets, change in platelet shape, release of stimulators from granules such as adenosine diphosphate (ADP) and thromboxane A2 (TXA2), recruitment of additional platelets, and aggregation of platelets. Importantly, these two pathways are interconnected. For example, thrombin, which cleaves fibrinogen to fibrin in the coagulation cascade pathway, is a powerful stimulator of platelet aggregation.[164] In addition, the activation of the coagulation cascade largely takes place on the surface of activated platelets.[164]

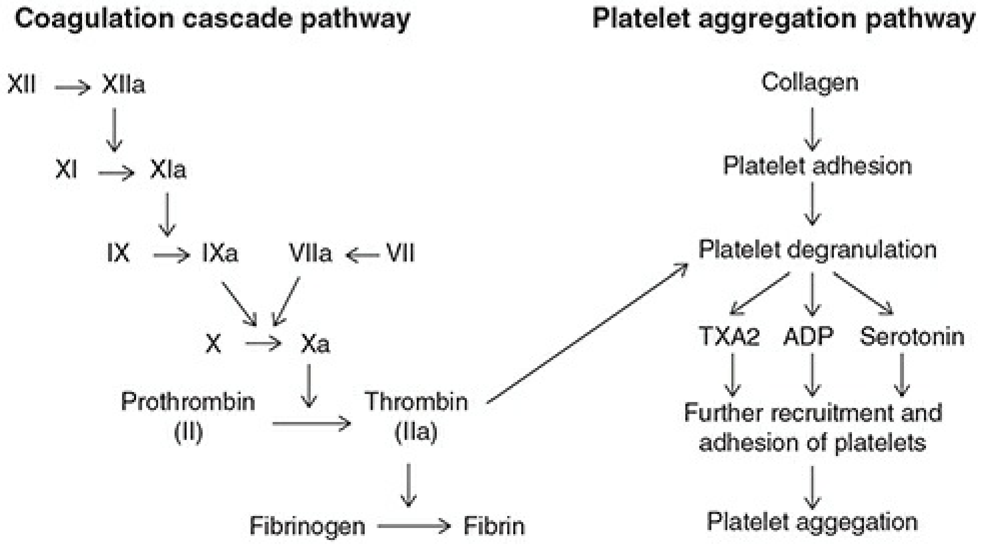

FIGURE 45-1 Coagulation Cascade and Platelet Aggregation Pathways

ADP = adenosine diphosphate, TXA2 = thromboxane A2.

ANTICOAGULANTS

Anticoagulants inhibit the activity or production of one or more serine proteases in the coagulation cascade pathway and can be divided into two groups: (1) drugs that directly block the activity of the pre-existing coagulation factors and (2) drugs that inhibit the production of coagulation factors (Table 45-3).

In the first group, some drugs inhibit one specific coagulation factor whereas others block multiple factors. Direct factor Xa inhibitors (apixaban, rivaroxaban, and edoxaban) inhibit only factor Xa. Low-molecular-weight heparins (LMWHs) block both factor Xa and thrombin, although they have a higher affinity for factor Xa.[165] UFH and LMWHs require an endogenous molecule, antithrombin, for full anticoagulation activity; antithrombin is necessary for these agents to inhibit both thrombin and factor Xa and provide an anticoagulant effect.[165]

The second group includes VKAs. Vitamin K is an essential cofactor for the posttranslational γ-carboxylation of glutamyl residues on the vitamin-K–dependent coagulation factors (II, VII, IX, and X). VKAs also target vitamin K epoxide reductase, a substance involved in the process of vitamin K recycling.[166,167] As a result, VKAs reduce the production of functional vitamin-K–dependent coagulation factors.

ANTIPLATELET DRUGS

Antiplatelet drugs can be divided into two groups according to their site of action in the platelet aggregation pathway. Agents in the first group antagonize stimulators of platelet aggregation, and those in the second group interfere with the binding of stimulated platelets to each other (Table 45-3).

Table 45-3 Mechanism of Drug-Induced Bleeding

Drugs	Mechanism
ANTICOAGULANTS	
Direct factor Xa inhibitors (apixaban, edoxaban, fondaparinux, rivaroxaban)	Inhibition of factor Xa
Direct thrombin inhibitors (argatroban, bivalirudin, dabigatran)	Inhibition of thrombin (factor II)
Low-molecular-weight heparin (e.g., dalteparin, enoxaparin, tinzaparin, etc.)	Inhibition of both thrombin and factor Xa
Unfractionated heparin	Inhibition of both thrombin and factor Xa
Vitamin K antagonists (acenocoumarol, fluindione, phenprocoumon, warfarin)	Depletion of coagulation factors II, VII, IX, and X
ANTIPLATELET DRUGS	
Anagrelide	Interference with maturation of megakaryocytes
Aspirin	Inhibition of production of TXA2 by inhibiting COX
Cilostazol	Inhibition of phosphodiesterase III
Dipyridamole	Inhibition of uptake of adenosine by platelets
Glycoprotein IIb/IIIa inhibitors (abciximab, eptifibatide, tirofiban)	Prevention of fibrinogen from binding by blocking glycoprotein IIb/IIIa receptors on platelets
P2Y12 receptor antagonists (cangrelor, clopidogrel, prasugrel, ticagrelor, ticlopidine)	Inhibition of adenosine diphosphate receptors on platelets
OTHER AGENTS	
Defibrotide	Increasing tissue-type plasminogen activator function and decreasing plasminogen activator inhibitor-1 activity
NSAIDs	Inhibition of production of TXA2 by blocking COX
SSRIs	Inhibition of serotonin uptake by platelets
Thrombolytics (alteplase, reteplase, tenecteplase)	Degradation of fibrin by activating plasminogen to plasmin
Vorapaxar	Prevention of thrombin from binding to protease-activated receptors on platelets

COX = cyclooxygenase, NSAID = nonsteroidal anti-inflammatory drug, SSRI = selective serotonin reuptake inhibitor, TXA2 = thromboxane A2.

Aspirin, clopidogrel, prasugrel, ticagrelor, cangrelor, ticlopidine, dipyridamole, vorapaxar, and cilostazole belong to the first group. Aspirin inhibits cyclooxygenase (COX), an enzyme important in generating TXA2, a stimulator of platelet aggregation. P2Y12 antagonists block the binding of ADP, another stimulator of platelet aggregation, to its receptors on platelets. Dipyridamole does not antagonize platelet receptors, but instead interferes with uptake of ADP into platelets. Thrombin stimulates the platelet aggregation pathway; it does this by binding to protease activated receptors (PAR) on platelets. Vorapaxar antagonizes

PAR on platelets. Cilostazol is a phosphodiesterase III inhibitor that increases the concentration of cyclic adenosine monophosphate, a secondary messenger important in preventing platelet aggregation. The second group, GPIIb/IIIa receptor antagonists, directly antagonizes the binding of fibrinogen to GPIIb/IIIa receptors on platelets, a critical step in platelet plug formation.

NSAIDs

Like aspirin, NSAIDs inhibit COX, reducing the production of TXA2.[168] Unlike aspirin, which is an irreversible COX inhibitor, NSAIDs are reversible inhibitors. As a result, their antiplatelet effect depends, in part, on their half-lives, and NSAIDs with short half-lives (e.g., ibuprofen) do not have sustained antiplatelet effects. As COX-1 is more responsible for generating TXA2, NSAIDs with a higher specificity for COX-2 (e.g., celecoxib) may have reduced antiplatelet effect compared to those without COX-2 selectivity.[169] Additionally, by inhibiting COX, aspirin and NSAIDs prevent the synthesis of prostaglandins and inhibit their mucosal-protective effects most notably in the gastrointestinal tract.[170]

SSRIs

SSRIs also exhibit an antiplatelet effect. Serotonin stimulates platelet aggregation. By inhibiting the uptake of serotonin into platelets, SSRIs interfere with this process. The antiplatelet effects of SSRIs may be weak because serotonin is a weak stimulator of platelet aggregation.[156]

THROMBOLYTICS

Thrombolytics are analogs of human tissue plasminogen activator (t-PA). Plasmin, an enzyme degrading fibrin, is converted from a precursor, plasminogen, and this conversion is facilitated by t-PA. Thrombolytics facilitate the degradation of fibrin.[171] Among the drug classes listed in Table 45-1, thrombolytics are generally considered to have the highest bleeding risk followed by anticoagulants, although direct comparison is lacking.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Abnormal laboratory values, changes in vital signs, and other physical findings (**Table 45-4**) can suggest the presence of bleeding. Decreased hemoglobin and hematocrit levels are common signs of bleeding and sudden drops in hemoglobin and hematocrit in a patient receiving a drug known to cause or exacerbate bleeding may indicate drug-induced bleeding.[160] Activated partial thromboplastin time (aPTT), prothrombin time (PT), and international normalized ratio (INR) can be elevated, particularly in patients receiving anticoagulants. A substantial loss of blood can compromise hemodynamics, resulting in hemorrhagic shock.[172]

Table 45-4 Signs and Symptoms Associated with Drug-Induced Bleeding

- Bruises, ecchymosis
- Decrease in blood pressure, increase in heart rate
- Decrease in hemoglobin and hematocrit levels
- Decreased or hazy vision, floating objects in the vision, blindness (bleeding in the eye)
- Dizziness, lightheadedness, fainting, loss of consciousness
- Elevation of coagulation test results (e.g., activated partial thromboplastin time, prothrombin time, international normalized ratio) in patients on an anticoagulant
- Fatigue, lethargy, coma
- Hematemesis, melena, hematochezia
- Hematuria
- Pain, swelling in the area of bleeding
- Positive guaiac test
- Symptoms of stroke (inability to speak, facial droop, inability to move part of body, nausea, vomiting, seizure)

Other signs and symptoms of bleeding may be site specific. A patient with gastrointestinal bleeding may present with melena and a positive guaiac test result, whereas a patient with intracranial bleeding may show symptoms of stroke (e.g., facial droop, inability to speak).[173,174] Pain can also occur if a hemotoma compresses an organ or nerve ending.

A careful medication history can help clinicians identify the most likely culprit drug(s) and the possible site(s) of bleeding. Additional laboratory tests (e.g., occult blood) and/or imaging modalities (e.g., computed tomography) can then be used to confirm the diagnosis.

Many disease states can cause signs and symptoms similar to those seen with drug-induced bleeding (**Table 45-5**), and some diseases can cause bleeding themselves. Iron-deficiency anemia and anemia of chronic disease, for example, decrease hemoglobin levels, and patients with end-stage liver disease typically have elevated INR values. In addition, ischemic stroke can cause symptoms that may be indistinguishable from those of drug-induced hemorrhagic stroke. Liver cirrhosis can lead to esophageal variceal bleeding by increasing portal vein pressure gradient, and bladder cancer can cause hematuria. Careful medical and medication histories as well as appropriate laboratory tests and imaging are essential to differentiate among the various causes and to arrive at a timely and accurate diagnosis.

Table 45-5 Conditions to Consider in the Differential Diagnosis of Drug-Induced Bleeding

- Anemia
- Cancer (bladder, colon, rectal)
- Esophageal variceal bleeding
- Hypotension
- Liver cirrhosis, end-stage liver disease
- Shock
- Stroke
- Syncope
- Trauma
- Tuberculosis

RISK FACTORS

Bleeding risk factors are summarized in **Table 45-6**. Common risk factors include older age, female sex, small body habitus, excessive anticoagulation, polypharmacy, prior history of bleeding, anemia, and liver or kidney disease.[175-177] With respect to invasive procedures, the duration of the procedure itself, the choice of access site (e.g., selection of the femoral versus radial artery during PCI), and the use of open versus laparoscopic/arthroscopic procedures can influence bleeding risk.[177-179]

Table 45-6 Risk Factors for Drug-Induced Bleeding

Common risk factors

- Age[175,177,180]
- Anemia[176]
- Body size (e.g., weight)
- Combination antithrombotic therapy (e.g., coadministration of antiplatelet drugs, NSAIDs, and/or anticoagulants)[178,179]
- Diabetes mellitus[183]
- Excessive alcohol intake[180]
- Hepatic dysfunction[180]
- History of bleeding[176,180]
- Hypertension[180]
- Initiation of an anticoagulant[175]
- Intensity of anticoagulation[175]
- Malignancy[180]
- Non-Caucasians[181]

- Previous stroke[97,180]
- Renal insufficiency[176,177]
- Sex[176,177]
- Thrombocytopenia[180,182]

Drug-specific risk factors

- Drug interactions increasing anticoagulation effect[184]

Warfarin:

  - *CYP2C9* reduced functional allele (e.g., **2, *3*)[185,186]
  - Decreased dietary intake of vitamin K (for VKA)
  - Labile INR[187]

Clopidogrel:

  - *CYP2C19* gain-of-function allele (e.g.,**17*)[188]

INR = international normalized ratio, NSAID = nonsteroidal anti-inflammatory drug, VKA = vitamin K antagonist.

Drug-specific bleeding risk factors include genetic polymorphisms and drug–drug interactions. Drugs have unique metabolic pathways, and genetic polymorphisms and concomitant administration of other drugs may influence a medication’s metabolic pathway in ways that increase bleeding risk. Warfarin is metabolized by cytochrome P450 (CYP) 2C9. Carriers of a dysfunctional *CYP2C9* allele, such as *CYP2C9*2* and **3*, have an increased risk of bleeding compared with *CYP2C9*1/*1* (wild-type allele).[185,189] Drugs that inhibit CYP2C9, such as fluconazole, metronidazole, amiodarone, and sulfamethoxazole–trimethoprim, can also increase the risk of bleeding in patients taking warfarin. Additionally, clopidogrel, a prodrug, is activated by CYP2C19. Carriers of the gain of function *CYP2C19*17* allele may have an increased risk of clopidogrel-associated bleeding compared with noncarriers of the allele because *CYP2C19*17* increases conversion of the inactive prodrug to active clopidogrel.[190]

Many risk assessment tools (e.g., HAS-BLED, HEMORR2HAGES, ATRIA) have been developed to stratify the risk of bleeding.[180,187,191] These tools have been validated in patients with atrial fibrillation; however, they may also prove useful in other situations such as in patients being treated for VTE.[180,187,191,192] Each tool utilizes a scoring system to assign a value to each risk factor, the summed total providing an assessment of overall bleeding risk, which can be labeled as low, intermediate, or high. For example, HAS-BLED, which predicts 1-year risk of major bleeding, assigns 1 point for the presence of a risk factor listed in **Table 45-7**. Patients with a score ≥3 are considered to be at high bleeding risk.

Table 45-7 HAS-BLED Risk Assessment Scoring Systems[187]

Hypertension	1 point
Abnormal kidney or liver function	1 point for each (2 max)
Stroke	1 point
Bleeding (history, anemia, predisposition)	1 point
Labile INR	1 point
Elderly (≥65 yr)	1 point
Drugs and alcohol	1 point (antiplatelet treatment) 1 point (≥8 drinks/wk) 2 points for both
A score of 3 or above indicates a high bleeding risk	

Which tool provides the best assessment of risk is currently unknown.[193-195] In addition, many of the risk factors incorporated into the tools are also risk factors for thrombosis (and are also included in tools used to stratify the risk of thrombosis). For example, the CHA2DS2VASc score, a tool used to predict the risk of ischemic stroke in patients with atrial fibrillation, includes blood pressure, history of previous stroke, and age in its risk assessment.[196] A patient who is predicted to have a high risk of thrombosis based on the CHA2DS2VASc score, therefore, would also likely have a high risk of bleeding using HAS-BLED, HEMORR2HAGE, or ATRIA scores. Clinicians should be aware of these limitations when using these tools.

MORBIDITY AND MORTALITY

Hemorrhage is the most common and significant adverse event associated with anticoagulants, antiplatelet drugs, NSAIDs, and thrombolytics; however, morbidity and mortality vary among the different classes and incidences are not well established. Bleeding morbidity and mortality associated with SSRIs is even less well characterized, but their common concomitant use with anticoagulants, antiplatelet drugs, and NSAIDs can affect these outcomes.[197-200]

ANTICOAGULANTS

Anticoagulants are widely accepted as high-risk drugs with respect to medication errors that can cause morbidity and mortality.[201] Major bleeding associated with therapeutic anticoagulation has been linked to increased length of hospital stay, higher total hospitalization costs, and higher costs for outpatient medical service and emergency department claims.[202] Intravenous (IV) UFH infusions in particular come with a high propensity for error and high mortality rates when compared to warfarin and LMWH.[201] Bivalirudin has been associated with a lower incidence of bleeding than UFH (used alone or with GPIIb/IIIa inhibitor) when used for PCI; however, the effect on mortality is not clear.[56,57,203] Major bleeding secondary to therapeutic parenteral anticoagulation with UFH or LMWH in the intensive care unit (ICU) has been shown to increase length of ICU stay, overall hospital stay, and in-hospital mortality.[204,205]

Warfarin consistently tops the list of medications implicated in adverse drug event-related emergency department visits and admissions.[206,207] The bleeding frequency associated with warfarin is approximately 15% to 20% per year, with life-threatening bleeds occurring at a rate of 1% to 3% annually.[208,209] Major bleeding mortality associated with warfarin has been reported as high as 15%.[210] Warfarin-associated ICH is especially serious because of its significant morbidity and mortality.[211] In a prospective study of patients admitted for ICH, patients receiving warfarin had earlier and higher rates of mortality than others, and those who survived the bleeding event had significantly higher costs and increased lengths of hospital stay.[212] There are likely many factors that influence mortality with warfarin. One study demonstrated warfarin use increased the incidence of ICH with age and INR >3.5 associated with a significant increase in mortality.[213]

Compared to warfarin, DOACs are associated with reduced all-cause, vascular, and bleeding mortality.[214] This benefit of reduced bleeding mortality, however, does not appear to apply to patients age 75 years or older.[215] In a single-center prospective cohort study of patients seen in the emergency department for severe bleeding from dabigatran, rivaroxaban, or apixaban, 83% were hospitalized with an average length of stay >1 week. Almost 30% of patients required an ICU level of care and 20% required reversal of the anticoagulant; 30-day mortality was 24% overall.[216] The costs associated with DOAC-related bleeding have not been well defined.[217] One study found DOAC-related bleeding was associated with shorter length of hospital stay compared to warfarin-related bleeding, a factor that could reduce the cost of treatment.[218] Nevertheless, the actual costs of treating DOAC-related bleeding are unknown because relatively few antidotes are available and experience with them is relatively limited.[219-221]

ANTIPLATELET DRUGS

Major bleeding post-PCI is associated with increased mortality and major adverse cardiovascular events, and bleeding secondary to the combination of antithrombotic medications used for acute coronary syndrome has been linked to increased mortality, nonfatal myocardial infarction, and stent thrombosis.[160,222] The concomitant use of GPIIb/IIIa inhibitors with UFH for PCI is correlated with more post-PCI bleeding than UFH or bivalirudin alone; however, bivalirudin has been associated with more ischemic events.[55] There is conflicting evidence regarding bleeding mortality associated with GPIIb/IIIa inhibitors for PCI, with some trials suggesting no increased risk over anticoagulation alone and others reporting significantly increased risk.[223,224]

With respect to oral antiplatelet therapy, prasugrel and ticagrelor are more potent than clopidogrel and have a higher association with bleeding.[97-100,225] However, the impact of these factors on morbidity and mortality is not well established. One study evaluated patients undergoing PCI for acute coronary syndrome and found no difference in in-hospital bleeding leading to prolonged hospital stay among clopidogrel, prasugrel, and ticagrelor. However, patients were followed for only 30 days post-PCI.[226] Cangrelor, an IV P2Y12 inhibitor, is associated with a higher risk of bleeding than clopidogrel; however, associated morbidity and mortality are unknown.[227] Further studies are needed to characterize the morbidity and mortality associated with the oral P2Y12 inhibitors.

NSAIDs AND ASPIRIN

The incidence of NSAID-induced bleeding depends on the drug and the dose. Higher risk of upper gastrointestinal bleeding is seen when daily doses of 2,400 mg ibuprofen, 100 mg diclofenac, 1,000 mg naproxen, and 20 mg piroxicam are used.[228] In patients who experience upper gastrointestinal bleeding secondary to NSAIDs (including aspirin), mortality is estimated at 20%.[229] Additionally, NSAIDs were associated with approximately 30% of hospitalizations due to adverse drug reactions in one study, with aspirin-related reactions accounting for the majority of cases.[230]

Aspirin use in the United States is widespread, with over 30% of adults age 40 years or older reporting taking preventive aspirin.[231] Aspirin can induce bleeding at any dose, and aspirin-induced moderate and major bleeding has been associated with increased all-cause mortality, which includes bleeding and cardiovascular related mortality.[232-234] Aspirin is commonly used concomitantly with other antiplatelet agents (e.g., GPIIb/IIIa inhibitors, P2Y12 inhibitors), and, although the combination increases the risk of bleeding and mortality, the extent of that effect has not been well defined.[235,236]

THROMBOLYTICS

Thrombolytic therapy is indicated for treatment of ischemic stroke, ST-segment elevation myocardial infarction (STEMI), and acute pulmonary embolism (PE); morbidity and mortality varies with indication. The rates of ICH associated with thrombolysis for stroke, STEMI, and acute PE are approximately 7%, 1%, and

1.5%, respectively.[237-240] Thrombolytic-associated ICH is best characterized in the stroke population where the mortality rate appears to range from 30% to 50%.[241,242] The average total cost of care for stroke in patients who receive thrombolysis ranges between $70,000–80,000, but the specific cost of managing thrombolytic complications and the impact on aspects such as hospital length of stay is unclear.[240]

SSRIs

Morbidity and mortality from bleeding associated with SSRIs are mostly described in patient populations with significant comorbidities (e.g., stroke, coronary artery bypass graft surgery, ICU admission), and outcomes vary from study to study.[199,200,243] One study suggested patients taking SSRIs prior to experiencing hemorrhagic stroke have increased stroke severity and mortality, and another study linked initiating SSRI therapy in patients admitted for peptic ulcer bleed to increased mortality.[197,199,200,243] More research is warranted to elucidate the actual impact of SSRI-associated bleeding.

PREVENTION

Prevention of drug-associated bleeding is multifaceted; general prevention strategies are included in **Table 45-8**. A key step in the prevention of drug-associated bleeding is to carefully weigh a patient's risk for bleeding (Table 45-6) against his or her risk for experiencing a thrombotic event prior to initiating therapy with a medication known to carry a risk of hemorrhage.

Appropriate laboratory monitoring is also important. Activated partial thromboplastin time is most commonly used to monitor IV UFH and direct thrombin inhibitor (DTI) therapy. Target aPTT values for UFH monitoring vary based on indication and type of reagent used in the laboratory; for DTI therapy, a target aPTT from 1.5 to 3 times the control is typically used.[249-251] A customary protocol for monitoring aPTT would include collection at the time of initiation of the infusion, 6 hours after initiation, 6 hours after any dosing rate changes, and then at least once daily if the patient remains at a constant drip rate.[250] Antifactor Xa can also be used to monitor IV UFH but is more typically used as a parameter to measure the anticoagulant effect of LMWH in special populations (e.g., patients with obesity).[252] The goal antifactor Xa range in adult patients is 0.6–1 anti-Xa units/mL for twice daily enoxaparin and >1 anti-Xa units/mL for once daily enoxaparin and dalteparin.[165,252]

Table 45-8 Approaches to Prevent Drug-Associated Bleeding

- Gastroprotective therapy (e.g., proton pump inhibitors are preferred over histamine receptor antagonists) is indicated in the following scenarios to prevent GI bleeding:[246-248]
    - Dual antiplatelet therapy + history of GI ulcer or bleed
    - Dual antiplatelet therapy + multiple risk factors for GI bleed (multiple concomitant NSAIDs, high-dose NSAIDs, concomitant anticoagulant, age >75, corticosteroid use, hemodialysis)
- Institutional order sets and protocols should be implemented for initiation, titration, and laboratory monitoring of continuous IV infusion unfractionated heparin or direct thrombin inhibitors
- Medications should be reviewed for renal dosing adjustments or contraindications to renal insufficiency (e.g., DOACs, parenteral DTIs, eptifibatide, tirofiban, NSAIDs)
- Patients receiving warfarin or DOACs should be educated regarding the indication/duration of therapy, monitoring, drug–drug interactions, drug–nutrition interactions, and signs and symptoms of bleeding
- Patients treated with LMWH should be educated on proper administration technique and, if appropriate, bridging instructions
- Polypharmacy should be avoided if possible (e.g., patients receiving warfarin therapy who undergo PCI may not need triple antithrombotic therapy with warfarin, aspirin, and clopidogrel[179,244,245])

DOAC = direct-acting oral anticoagulant, DTI = direct thrombin inhibitor, GI = gastrointestinal, IV = intravenous, LMWH = low-molecular-weight heparin, NSAID = nonsteroidal anti-inflammatory drug, PCI = percutaneous coronary intervention.

INR, which is derived from PT, is the gold standard for monitoring VKA therapy. Indication determines the desired target INR, and INR should be monitored regularly.[253-255] In the hospital, patients on warfarin should receive daily INR monitoring until therapeutic for at least two consecutive results.[253] Once this is achieved and the patient is on a stable dose, less frequent monitoring can be employed. In the outpatient setting, monitoring is more frequent for patients starting therapy (e.g., once every few days) and can be less frequent for patients who are stable (e.g., every 4–6 weeks).[256]

Although DOACs are marketed as not requiring any coagulation laboratory monitoring, some situations (e.g., need for emergent surgical procedures or concern regarding possible overanticoagulation) require measurements to be made. In the RE-LY trial, steady-state trough concentrations for patients taking dabigatran 150 mg twice daily ranged from approximately 40 ng/mL to 215 ng/mL; however, these concentrations have not been correlated with clinical outcomes to permit use in therapeutic monitoring.[257] PT and INR are increased by dabigatran but are insensitive to high concentrations.[258-260] Diluted thrombin clotting time and ecarin clotting time correlate linearly to dabigatran concentrations but are not yet widely available.[259,260] Specific anticoagulation laboratory parameters have been investigated for factor Xa inhibitor monitoring. Chromogenic antifactor Xa assays correlate linearly with direct Xa inhibitor plasma concentrations and utility may increase as more data accumulate.[261,262] Unfortunately, none of these laboratory values or assays has been clinically proved to predict therapeutic effectiveness or incidence of bleeding. As a result, to help optimize safety, clinicians should be familiar with DOACs pharmacokinetic properties (**Table 45-9**). For example, all DOACs are excreted to some extent by the kidney, so creatinine clearance can be used to help anticipate and avoid drug accumulation. Additionally, an understanding of the metabolism of these medications can help clinicians identify and avoid potential interacting medications that can increase anticoagulant effect.

Table 45-9 Dosing and Pharmacokinetic Properties of DOACSs

	Dabigatran	Rivaroxaban	Apixaban	Edoxaban
Typical standard dose	150 mg twice daily	20 mg daily (15 mg twice daily for first 3 weeks of VTE treatment)	5 mg twice daily	60 mg daily
Half-life (h)	12–17	5–9 11–13 (elderly)	12	10–14
Time to peak plasma concentration (h)	2	2–5	1–3	1.5
Urinary excretion (%)	80	35	27	50
Renal dosing adjustment	75 mg twice daily for CrCl 15–30 mL/min	15 mg daily for CrCl 15–50 mL/min	2.5 mg twice daily if two risk factors: age ≥80, body weight 60 kg, SCr ≥1.5 mg/dL, concomitant CYP3A4 and P-gp inhibitors	• Avoid for CrCl >95 mL/min • 30 mg daily for CrCl 15–50 mL/min
Protein binding	35%	92–95%	87%	55%
Drug interactions requiring dose adjustment	• Concomitant P-gp inducer (rifampin), contraindicated VTE Indication • Any P-gp inhibitor,[a] avoid use AF Indication • Dronedarone or ketoconazole and CrCl 30–50 mL/min and atrial fibrillation indication, reduce dose to 75 mg twice daily • Any P-gp inhibitor[a] and CrCl <30 mL/min; avoid use	Concomitant strong P-gp and CYP3A4 inhibitors[b]; avoid use	Concomitant strong P-gp and CYP3A4 inhibitors[c]; reduce apixaban dose by 50% (to 2.5 mg twice daily)	Concomitant P-gp inhibitor,[d] reduce dose to 30 mg

AF = atrial fibrillation, CrCl = creatinine clearance, DOAC = direct-acting oral anticoagulant, P-gp = P-glycoprotein, VTE = venous thromboembolism.

[a] Amiodarone, clarithromycin, dronedarone, quinidine, verapamil.

[b] Ketoconazole, itraconazole, posaconazole, ritonavir.

[c] Clarithromycin, ketoconazole, itraconazole, ritonavir.

[d] Verapamil, quinidine; the short-term use of azithromycin, clarithromycin, erythromycin, oral itraconazole, oral ketoconazole.

There are no specific therapeutic drug-monitoring parameters for antiplatelet drugs, thrombolytics, or SSRIs; however, standard hematology laboratory values (e.g., hemoglobin, hematocrit, platelets, etc.) should be assessed. Renal function should also be evaluated at baseline and periodically for patients on regular NSAID therapy.

There are a number of prophylactic measures that can be effectively used to minimize bleeding risk. Medication regimens that increase the risk of gastrointestinal bleeding may necessitate the addition of gastroprotective therapy. Patients requiring DAT following myocardial infarction should receive gastroprotective therapy with a proton pump inhibitor (PPI) if they have a history of gastrointestinal bleeding, concomitant anticoagulant therapy, and/or chronic NSAID or corticosteroid use.[247,263] PPIs have been shown to have better protective effects than the histamine receptor antagonists.[247,264] There is, however, controversial evidence that PPIs interact with antiplatelet regimens by decreasing the antithrombotic effects and increasing the risk for cardiovascular events.[263,265-267]

MANAGEMENT

Management of drug-induced bleeding requires both nonpharmacological and pharmacological measures to achieve hemostasis and/or reversal of anticoagulant effect. Nonpharmacological measures are listed in **Table 45-10**.

Table 45-10 Nonpharmacological Measures for Management of Drug-Associated Bleeding[268,269]

- Apply pressure to the source of bleeding, if possible, and stop the offending agent
- Assess hepatic and renal function; estimate half-life and time to washout of offending agent
- Obtain information regarding timing and amount of last dose of offending agent
- Order complete blood cell count and other pertinent anticoagulation laboratory values (e.g., aPTT, PT/INR, antifactor Xa) as appropriate to assess level of antithrombotic effect
- Plan for radiological interventions, endoscopy, or surgery as appropriate

aPTT = activated partial thromboplastin time, INR = international normalized ratio, PT = prothrombin time.

ANTICOAGULANTS

Hemostasis is most rapidly achieved via administration of hemostatic agents (e.g., prothrombin complex concentrates [PCCs], fresh-frozen plasma [FFP]) and, if available, targeted reversal agents (e.g., idarucizumab, vitamin K, and protamine). Severity, site of hemorrhage, and time frame for achieving hemostasis should guide reversal strategy; not all bleeding requires administration of hemostatic agents, and caution should be exercised given the risk of thrombotic adverse events associated with some agents.[269-271] **Table 45-11** lists characteristics of reversal agents, and **Figures 45-2** and **45-3** describe anticoagulant reversal strategies.

Table 45-11 Characteristics of Reversal Agents and Hemostatic Agents

Agent	Mechanism	Dose	Kinetics
REVERSAL AGENTS			
Idarucizumab	Monoclonal antibody directly neutralizes the effects of dabigatran	2.5 g × 2 IV boluses (5 g total) within 15 minutes of each other	Onset: • Immediate Duration: • Up to 24 hours
Protamine	Binds heparin molecules to form inactive salt	For IV unfractionated heparin: 1 mg protamine per 100 units of heparin, (max dose 50 mg) • Must account for UFH infused over preceding 2–3 hours • Use 0.5 mg/100 units IF drip is held >60 minutes • Use 0.25 mg/100 units IF drip held >2 hours For LMWH: 1 mg/100 anti-Xa units within 8 hours of last enoxaparin dose or 24 hours of dalteparin dose	Onset: • ~5 minutes
Vitamin K (phytonadione)	Cofactor for hepatic production of factors II, VII, IX and X	Variable: • 2–2.5 mg PO vitamin K is recommended for INR >10 without bleeding • Low doses of IV vitamin K (e.g., 0.5–1 mg) are effective in causing partial reversal at 24–48 hours	Onset: • PO 12–24 hours • IV 4–12 hours
HEMOSTATIC AGENTS			
3-factor prothrombin complex concentrate (PCC-3)	Replaces coagulation factors II, IX, and X, in concentrations 25 times that of FFP	For warfarin: • INR <2: 20 units/kg • INR 2–4: 30 units/kg • INR >4: 50 units/kg For dabigatran or factor Xa inhibitor: Up to 50 units/kg	Onset: • ~5–15 minutes Duration: 12–24 hours
4-factor prothrombin complex concentrate (PCC-4)	Replaces coagulation factors II, VII, IX, and X, in concentrations 25 times that of FFP	For warfarin: • INR 2 to <4: 25 units/kg (maximum dose 2,500 units) • INR 4–6: 35 units/kg (maximum dose 3,500 units) • INR >6: 50 units/kg (maximum dose 5,000 units) For dabigatran or factor Xa inhibitor: • Up to 50 units/kg	Onset: • ~5–15 minutes Duration: • 12–24 hours
Activated PCC (e.g. factor eight inhibitor bypass activity [FEIBA])	Replaces coagulation factors II, IX, X, and activated VII	8–25 units/kg[273]	Onset: • ~5–15 minutes Duration: • 8–12 hours
Fresh-frozen plasma (FFP)	Replaces coagulation factors lowered by warfarin (II, VII, IX, and X) at lower concentration than PCCs	5–20 mL/kg IV (~10 mL/min)	Onset: • ~1–4 hours Duration: • ≤6 hours
Recombinant activated factor VII (rFVIIa)	Replaces activated factor VII	2nd-line therapy for fondaparinux: 90 mcg/kg[a]	Onset: • ~5–10 minutes Duration: • 4–6 hours

INR = international normalized ratio, IV = intravenous, LMWH = low-molecular-weight heparin, PCC = prothrombin complex concentrate, UFH = unfrationated heparin.

[a] Doses of 1 mg IV are typically sufficient.[272]

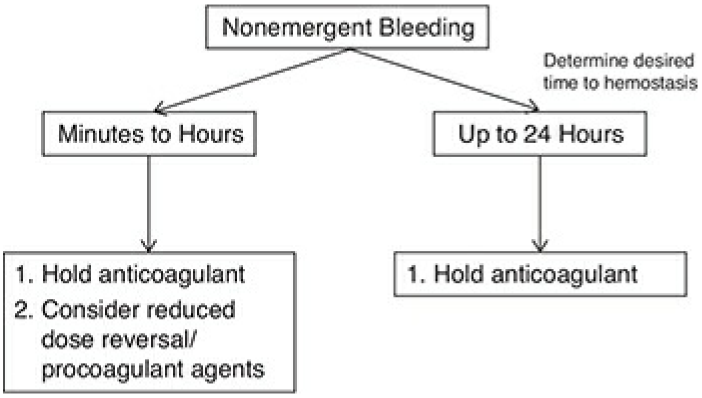

FIGURE 45-2 Oral Anticoagulant Reversal Algorithm: Nonemergent Bleeding

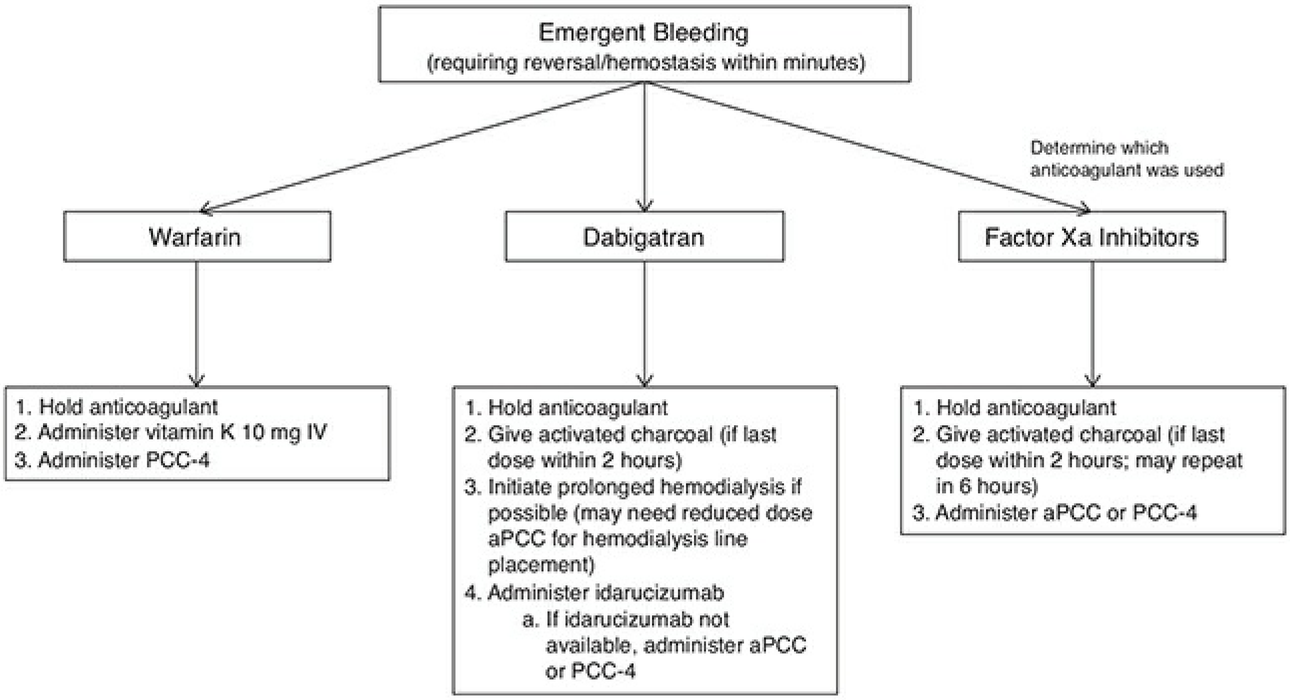

Emergent Bleeding
(requiring reversal/hemostasis within minutes)
Determine which anticoagulant was used
Warfarin
Dabigatran
Factor Xa Inhibitors
1. Hold anticoagulant
2. Administer vitamin K 10 mg IV
3. Administer PCC-4
1. Hold anticoagulant
2. Give activated charcoal (if last dose within 2 hours)
3. Initiate prolonged hemodialysis if possible (may need reduced dose aPCC for hemodialysis line placement)
4. Administer idarucizumab
a. If idarucizumab not available, administer aPCC or PCC-4
1. Hold anticoagulant
2. Give activated charcoal (if last dose within 2 hours; may repeat in 6 hours)
3. Administer aPCC or PCC-4

FIGURE 45-3 Oral Anticoagulant Reversal Algorithm: Emergent Bleeding

aPCC = activated prothrombin complex concentrate, IV = intravenous, PCC-4 = 4-factor prothrombin complex concentrate.

For heparin-related hemorrhage, protamine is the agent of choice; however, protamine should only be used to reverse therapeutic doses of UFH or LMWH.[274] When managing bleeding associated with IV UFH, the length of time the patient has been receiving the infusion, whether or not therapeutic aPTT values have been achieved, and when the infusion was stopped should be considered. Additionally, clinicians must account for the amount of UFH infused over the 2–3 hours preceding discontinuation of the drip. The maximum dose of protamine is 50 mg due to a paradoxical anticoagulant effect that can occur at high doses.[275,276] It is important to note that protamine only partially reverses LMWHs.[277] The timing of the last LMWH dose must be determined because protamine should only be used within 8 hours of the last enoxaparin dose or within 24 hours of last dalteparin dose.[274]

Vitamin K is central to the management of warfarin-associated bleeding. It is available in oral, subcutaneous, and IV formulations. Oral vitamin K is preferred for nonemergent, minor bleeding or for patients presenting without bleeding but with an INR >10.[278] Because oral vitamin K has a slower onset of action and subcutaneous vitamin K has erratic absorption properties, IV vitamin K is preferred for the management of emergent, major bleeding.[274,278,279] The dose of IV vitamin K typically ranges from 0.5 mg to 10 mg, with larger doses associated with a longer duration of action but not a greater INR reduction.[280] For management of warfarin-associated ICH, an IV dose of 10 mg is recommended.[274] Because vitamin K does not have an immediate onset, it should be used with a hemostatic agent to manage emergent, major bleeding. Prothrombin complex concentrates are considered first line for warfarin-associated ICH and are dosed based on INR.[274] FFP should only be used if PCCs are not available or are contraindicated.

Idarucizumab is the first-line agent for treating dabigatran-associated ICH.[274] It is a monoclonal antibody that directly binds dabigatran, and dabigatran's affinity for idarucizumab is approximately 350 times greater than its affinity for thrombin. It is administered in two 2.5-g bolus doses (total dose 5 g) that should be given no more than 15 minutes apart. Idarucizumab should be given within 3–5 half-lives (approximately 24 hours) of the last dabigatran dose in patients with normal renal function. For patients with renal insufficiency, idarucizumab can be given without regard to the last dabigatran dose. If idarucizumab is not available or is contraindicated, activated PCC (aPCC) or 4-factor PCC (PCC-4) can be utilized. Because dabigatran is not highly protein bound, it can be removed via hemodialysis. However, prolonged hemodialysis is required to avoid rebound anticoagulant effect.[281] In addition, insertion of a dialysis catheter may increase a patient's risk for further bleeding.

Both aPCC and PCC-4 are considered first-line agents for managing factor Xa inhibitor-associated ICH and, like idarucizumab for dabigatran, should be given only within 3–5 half-lives of the last factor Xa inhibitor dose.[274] Activated charcoal is also recommended if the last dose of dabigatran or factor Xa inhibitor was within 2 hours.

Prior to the availability of PCC-4, recombinant activated factor VII (rFVIIa) was recommended for reversal of warfarin-associated bleeding. However, given its higher associated risk of myocardial infarction and thrombosis, its use in managing anticoagulant-associated bleeding is limited to second-line therapy for fondaparinux-related bleeding.[274] First-line therapy for fondaparinux-associated ICH is aPCC. Additionally, rFVIIa can also be considered for reversal of parenteral DTI-associated bleeding, although given the relatively short half-life of these agents, simply stopping the infusion may be sufficient in achieving hemostasis.[274,282]

As previously described, hemostatic agents may increase the risk for thrombotic events, and reversing the effects of anticoagulant agents will also increase a patient's risk for thrombosis. Furthermore, all DOACs have a boxed warning for premature, abrupt discontinuation leading to increased risk of thrombotic event.[283,284] Thus, when managing anticoagulant-associated bleeding, clinicians should continue to consider patients' risks for thrombosis and factor restarting anticoagulation therapy into treatment plans.

ANTIPLATELET DRUGS, ASPIRIN, AND NSAIDs

Strategies to manage antiplatelet-associated bleeding include general nonpharmacologic measures, and in cases of critical bleeding, platelet transfusion.[268,274] To avoid pharmacologic inhibition of transfused platelets, transfusion should occur 3–5 half-lives after the last antiplatelet dose. Desmopressin can be considered and is administered intravenously as a single dose of 0.4 mcg/kg.[274]

It should be noted that platelet transfusion is ineffective at reversing GpIIb/IIIa inhibitors, but because of their short half-lives, management of GpIIb/IIIa-associated bleeding typically requires only discontinuation of the agent and supportive care. Similarly, NSAID-associated hemorrhage is managed primarily by discontinuation of the offending agent along with nonpharmacologic and supportive measures.

THROMBOLYTICS

Several mechanisms are involved with fibrinolytic/thrombolytic-associated bleeding, so management strategies employ several different agents. Institutional protocols typically include the use of FFP, cryoprecipitate (10 units), vitamin K, platelets, and antifibrinolytics (aminocaproic acid 4–5 g or tranexamic acid 10–15 mg/kg).[268,274,285-288]

INFORMATION FOR PATIENTS

Patient education is crucial to the prevention of drug-associated bleeding. Patients should be familiar with how the various medications will impact their activities of daily living and should be taught to detect signs and symptoms of major or minor bleeding. It is imperative that patients understand when to seek medical treatment. For patients receiving anticoagulation therapy, providers can consider recommending patients follow up at an anticoagulation clinic. Education programs are key elements of these clinics, and anticoagulation clinic patients receiving warfarin experience fewer adverse events.[289-291]

Providers should discuss the risks of polypharmacy with patients. Patients should be encouraged to share updated medication lists (including nutritional supplements and over-the-counter medications) with all healthcare professionals involved in their care.

CHAPTER 46

Thrombocytopenia

Kellie Jones Weddle and Patrick J. Kiel

Thrombocytopenia is typically defined as a platelet count <150,000/mm^3 or a >50% decrease in the count from baseline.[1] Thrombocytopenia is considered to be moderate when the platelet count is 20,000–150,000/mm^3 and severe when the platelet count falls to <20,000/ mm^3. Patients with severe thrombocytopenia risk serious bleeding and even death.

Drug-induced thrombocytopenia is often a diagnosis of exclusion. Laboratory confirmation of drug-induced thrombocytopenia is an unusually difficult task because of the unavailability of drug-dependent antiplatelet antibodies for testing. Nondrug causes (e.g., viruses, intravascular coagulation disorders, or autoimmune disorders) must always be ruled out and pseudothrombocytopenia and dilutional thrombocytopenia should be excluded as potential causes as well.[2] A careful review of the patient's medication history (including current medications and any recent changes as well as nonprescription medications, herbal and/or nutritional supplements) is essential to help identify and address all potential causes of drug-induced thrombocytopenia. Although thrombocytopenia is listed as a possible adverse effect of many medications, it is actually considered a rare event.

CAUSATIVE AGENTS

There are many nondrug causes of thrombocytopenia, including human immunodeficiency virus, disseminated intravascular coagulation, blood transfusions, lupus, and sepsis.[3] In addition, many herbal supplements have been documented to cause precipitous drops in platelet counts. Although discussion of these conditions and agents is beyond the scope of this chapter, all should be considered as possible causes in any patient with thrombocytopenia. Numerous commonly prescribed drugs have been associated with thrombocytopenia and, in 1998, George and colleagues published an extensive review of drugs known to cause this disorder.[4] This database has continually been updated to include newer drugs, with the last update published in 2012.[5] Classes of medications known to cause thrombocytopenia include the cinchona alkaloids, antimicrobial agents, platelet inhibitors, antirheumatic agents, anticonvulsants, analgesics, heparins, chemotherapeutic agents, and immunosuppressants.[6] **Table 46-1** lists agents implicated in drug-induced thrombocytopenia. Many chemotherapeutic agents also cause thrombocytopenia, although, in contrast to the agents listed in Table 46-1, the thrombocytopenia that occurs during chemotherapy is generally predictable and represents an expected consequence of therapy.

Table 46-1 Agents Implicated in Drug-Induced Thrombocytopenia

Drug	Incidence	Level of Evidence[a]
Abciximab74	0.5–1%: first exposure 10–14%: second exposure	A
Acetaminophen4	NK	C
Adefovir dipivoxil5	NK	C
Alfuzocin5	NK	C
Alprenolol4	NK	C
Aminoglutethimide4	NK	C
Amiodarone4	NK	C
Aminosalicylic acid4	NK	C

Chlordiazepoxide–clidinium bromide[75]	NK	C
Chlorothiazide[4]	NK	C
Chlorpromazine[4]	NK	C
Chlorpropamide[4]	NK	C
Cimetidine[4]	NK	C
Danazol[4]	NK	C
Diazepam[4]	NK	C
Diatrizoate meglumine[76]	<1%	C
Diazoxide[4]	NK	C
Deferoxamine[4]	NK	C
Diclofenac[4]	<1%	C
Digoxin[4]	NK	C
Efalizumab[77]	0.3%	A
Ethambutol[4]	NK	C
Etretinate[5]	NK	C
Eptifibatide[74]	0.2–0.5%	A
Famotidine[5]	NK	C
Fenofibrate[83]	NK	C
Fluconazole[4]	NK	C
Glyburide[3]	NK	C
Gold salts[4]	1–2%	C
Haloperidol[14]	NK	C
Heparin[6]	3–6%	A
Hydrochlorothiazide[4]	NK	C
Interferon α[4]	NK	C
Ibuprofen[6]	<1%	C
Iloprost[5]	NK	C
Isoniazid[4]	NK	C
Linezolid[54]	21%	C
Levamisole[4]	NK	C
Lopinavir/ritonavir[5]	NK	C
Methyldopa[4]	NK	C

Minoxidil[4]	NK	C
Meloxicam[82]	NK	C
Moxifloxacin[81]	NK	C
Nalidixic acid[4]	NK	C
Naphazoline[4]	NK	C
Naproxen[74]	<1%	C
Nitroglycerin[4]	NK	C
Octreotide[74]	NK	C
Oxprenolol[4]	NK	C
Pentoxifylline[84]	NK	C
Phenytoin[4]	NK	C
Piperacillin[4]	NK	C
Procainamide[6]	1%	C
Quinidine[4]	<1%	C
Quinine[4]	<1%	C
Ranitidine[4]	NK	C
Rifampin[4]	NK	C
Simvastatin[78]	<0.1%	C
Sulfasalazine[79]	<1%	C
Sulindac[4]	<1%	C
Tamoxifen[4]	NK	C
Terbinafine[75]	NK	C
Thiothixene[4]	NK	C
Tirofiban[75]	0.2–0.5%	A
Tolmentin[4]	<1%	C
Trimethoprim–sulfamethoxazole[4]	NK	C
Sulfisoxazole[4]	NK	C
Valproate[53]	20%	C
Vancomycin[80]	NK	A

NK = not known.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level

C—evidence from one or more published case reports or case series.

EPIDEMIOLOGY

Although the exact incidence of drug-induced thrombocytopenia is not known, it is estimated to be approximately 10 cases per 1 million people per year.[3,6] The risk of thrombocytopenia in patients receiving trimethoprim–sulfamethoxazole is reported to be 38 occurrences per 1 million users and in patients receiving quinine or quinidine, the risk is reported to be 26 occurrences for every 1 million users.[6]

MECHANISMS

Mechanisms of drug-induced thrombocytopenia are diverse and can involve both immunologic and nonimmunologic processes (**Table 46-2**).

Table 46-2 Mechanisms of Drug-Induced Thrombocytopenia

Drug	Mechanism
Abciximab, eptifibatide, tirofiban[6,25]	Drug-dependent antibody recognition of Fab fragment and glycoprotein IIb/IIIa neoepitope
Chloramphenicol,[54] linezolid[54]	Mitochondrial respiration suppression
Gold salts, procainamide[6,17,18]	Autoantibodies
Heparin, low-molecular-weight heparin[6,21-24]	Antibodies targeting epitope formation of heparin and Platelet Factor 4
Penicillins, cephalosporins and respective metabolites[6-8]	Hapten formation
Quinine, quinidine, sulfonamides[6,12] Nonsteroidal anti-inflammatory drugs, acetaminophen (paracetamol)	Compound epitope formation
Valproic acid, amiodarone[52,53]	Nonidiosyncratic concentration-dependent
Vancomycin[80]	Vancomycin-dependent antibodies against glycoprotein IIb/IIIa and unknown glycoproteins

DRUGS AS HAPTENS

Covalent bonding between drug molecules (haptens) and autologous proteins has been implicated in the production of drug-protein–specific antibodies.[7-9] Evidence is insufficient to support this as the mechanism responsible for drug-induced thrombocytopenia, however, except in the cases of mild hemolytic anemia and rare instances of penicillin-induced thrombocytopenia.[10] In general, antibodies are not directed toward a drug (hapten) that is covalently bound to platelets. The “innocent bystander hypothesis,” which suggests that an antibody directed toward a drug molecule somehow cross-reacts with platelets resulting in thrombocytopenia has largely been refuted.[11]

COMPOUND EPITOPE FORMATION

Quinine, quinidine, sulfonamide antibiotics, and nonsteroidal anti-inflammatory drugs or all their respective metabolites may induce thrombocytopenia through the formation of new epitope (part drug, part protein) compound.[6,12] Over a century ago, quinine was the first drug recognized to cause severe thrombocytopenia. Initially used for the treatment of malaria, quinine can also be found in common tonic water, which may be consumed alone or mixed with alcohol for consumption. Quinine is also sometimes used to treat nocturnal leg cramps, although this use is not approved by the U.S. Food and Drug Administration (FDA) due to the risk of adverse reactions.[13]

Quinine is thought to cause glycoprotein (GP) structural modifications via one of two possible mechanisms. First, the soluble drug may react with the GP in a complementary manner with respect to charge or hydrophobic domain.[6,14] An antibody may then interact with the drug and adjacent peptides, resulting in platelet destruction.[11] A second widely accepted possible mechanism is that drug binding occurring at one locus induces a structural modification on a GP at another locus, leading to antibody binding and subsequent lysis.[11] It is known that the fragment antigen binding (Fab) region of the antibody is responsible for drug-dependent antibody binding.[15] The epitopes targeted by these antibodies include GPIIb/IIIa or GPIb/V/IX complexes.[10,14,16]

DRUG-INDUCED AUTOANTIBODIES

Rarely, autoantibodies are capable of destroying platelets after drug exposure. Such is the case in approximately 1–3% of patients receiving gold therapy for rheumatoid arthritis. The onset of gold-induced thrombocytopenia can be either rapid or delayed.[17] Patients may present with a sudden drop in platelets, or the platelet count may gradually decline over weeks to months. Delayed onset may be associated with pancytopenia. Sudden thrombocytopenia has been likened to idiopathic thrombocytopenia purpura (ITP), in which there is acute onset of immune-mediated platelet destruction with normal megakaryocytes found on bone marrow biopsy.[17] Through an unknown mechanism, gold stimulates immunoglobulin G (IgG) to target glycoprotein V on platelets.[10,18] This autoimmune-mediated reaction is independent of gold serum concentrations and may temporarily persist even after the drug is discontinued.[18] Similar occurrences have been described with procainamide but without known GP targets.[19,20]

HEPARIN-INDUCED THROMBOCYTOPENIA

Type II heparin-induced thrombocytopenia (HIT) is a result of antibodies targeting the epitope formation of heparin and platelet factor 4 (PF4), as opposed to HIT Type I which is benign and nonimmune mediated.[21,22] PF4 is a cytokine found in platelet α-granules and is released in response to platelet aggregation. It is thought that PF4 is involved in coagulation, inflammation, and chemotaxis and occurs in 1–3% of patients exposed to heparin products.[22] Heparin forms a complex with PF4, leading antibodies to recognize this entity as a new epitope.[22-24] Heparin may also cause conformational changes on PF4, where antibodies might be recognized as "foreign," or vice versa.[22] It is known that IgG, IgM, and IgA antibodies are responsible for HIT, with IgG being the most prevalent.[22,24] Although patients with HIT have circulating immunoglobulins for the heparin–PF4 complex, there are patients with the same immunoglobulins who do not present with HIT.[22] Thrombosis results from PF4 binding to glycosaminoglycan on endothelial cells, leading to the initiation of HIT antibodies targeting those cells. The apoptosis of endothelial cells leads to subsequent platelet activation and procoagulant reactions.[22] Platelet activation leads to microparticle release and further thrombosis stimulation. HIT can occur regardless of the dose, route, or frequency of administration of heparin products.

FIBRINOGEN INHIBITORS

Abciximab, tirofiban, and eptifibatide antagonize fibrinogen at GPIIb/IIIa, thereby inhibiting platelet–fibrinogen interactions and subsequent thrombus formation.[25] These agents are used in patients undergoing percutaneous transluminal coronary angioplasty to prevent restenosis.[26-29] Fibrinogen inhibitors cause thrombocytopenia within hours of administration in approximately 1% of patients after first exposure and in 4% after second exposure.[27,29]

Abciximab is a chimeric Fab fragment derived from a murine monoclonal antibody, 7E3. Acute thrombocytopenia, characterized by a decrease in platelet count that develops within hours after drug administration, is thought to be caused by pre-existing antibodies directed toward murine components of abciximab.[6,29] Compared with other fibrinogen inhibitors, abciximab is associated with a more severe thrombocytopenia, with platelet counts decreasing to $<10{,}000/\text{mm}^3$. Delayed thrombocytopenia is characterized by a decrease in platelet count that develops within a week after drug administration and may occur upon re-exposure via newly induced IgG or IgM antibodies that possibly recognize epitopes on abciximab-coated platelets.[26,29]

A number of factors have been associated with an increased risk of thrombocytopenia in patients receiving a fibrinogen inhibitor, including the concomitant administration of aspirin or heparin and the use of intra-aortic balloon pumps.[30,31] Tirofiban and eptifibatide bind to the Arg-Gly-Asp recognition sites on GPIIb/IIIa, thereby antagonizing fibrinogen binding and subsequent platelet aggregation via platelet–fibrinogen–platelet interactions.[25] Specific antibodies recognizing drug binding at GPIIb/IIIa have not been identified as a definitive pathogenesis. Drug-dependent antibodies may recognize several epitopes because of conformational changes conferred from tirofiban or eptifibatide binding.[25,27] Nonimmune-mediated thrombocytopenia has also been discussed as a possible cause, but exact mechanisms have not been identified.[25]

HISTAMINE-RECEPTOR ANTAGONISTS

Case reports have implicated histamine-receptor antagonists as a possible trigger for thrombocytopenia.[32] Most reported cases occurred in intensive care units when the agents were used for stress-related mucosal injury prophylaxis. Proposed mechanisms include bone-marrow suppression via inhibition of stem-cell differentiation and formation of IgG antibodies.[32] However, well-designed retrospective and prospective studies have failed to confirm that histamine-receptor antagonists are a cause of thrombocytopenia in critically ill patients.[33,34]

THROMBOTIC THROMBOCYTOPENIC PURPURA

Thrombotic thrombocytopenic purpura–hemolytic uremic syndrome (TTP-HUS) is an inclusive term used to describe multiple causes of a clinicopathologic disorder with a fatality rate of 90%. This disorder is characterized by microangiopathic hemolytic anemia, erythrocyte fragmentation (schistocytes), thrombocytopenia, and other clinical features.[35,36] Ensuing complications include renal failure, neurologic abnormalities, bleeding, and fever. TTP-HUS can occur as a result of von Willebrand factor–cleaving protease deficiency, infections with *Escherichia coli* O157:H7, hematopoietic stem-cell transplantation, and certain drugs.[35,37-39] Evidence for drug-induced TTP-HUS exists for mitomycin C, cyclosporine, tacrolimus, sirolimus, quinine, ticlodipine, clopidogrel, and simvastatin.[35,36,40-45]

Drug-induced TTP has been postulated to occur via endothelial damage leading to subsequent platelet aggregation, such as with mitomycin C, cyclosporine, tacrolimus, and sirolimus.[36,43] In addition, these agents are thought to cause TTP in a dose-dependent manner.[36] In contrast, quinine-induced TTP is thought to be mediated by antibodies in the presence of soluble drug.[40] Quinine-induced TTP has been described after brief and even single exposures and is thought to be antibody-mediated, although antibodies directed toward von Willebrand factor–cleaving protease have not been reported.[36,38,40] Ticlopidine- and clopidogrel-induced TTP are somewhat paradoxical; case reports suggest an association with TTP, but mechanisms have not been elucidated.[42,44,45] Also, the reported incidence of TTP associated with these drugs appears to be similar to the incidence of TTP found in the general population (<1%).[36]

Table 46-3 Signs and Symptoms Associated with Drug-Induced Thrombocytopenia[6,22,52]

Systemic symptoms

- Chills
- Dizziness
- Fatigue
- Fever
- Nausea/vomiting

Moderate thrombocytopenia (20,000–150,000 platelets/mm^3)

- Ecchymosis
- Microscopic hematuria
- Petechiae
- Purpura

Severe thrombocytopenia (<20,000 platelets/mm^3)

- Central nervous system hemorrhage
- Epistaxis
- Florid purpura
- Gingival bleeding
- Gross hematuria
- Hematochezia
- Menorrhagia
- Retroperitoneal bleeding

Heparin-induced thrombocytopenia–specific symptoms

- Anaphylaxis
- Gangrene
- Skin necrosis
- Upper and lower extremity deep-vein thrombosis or pulmonary embolism

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Usually patients presenting with drug-induced thrombocytopenia have been exposed to the culprit agent for approximately 1–2 weeks; however, symptoms may develop immediately after exposure (**Table 46-3**). Patients may present with petechiae, ecchymosis, and purpura. With more severe thrombocytopenia, patients may experience epistaxis, hematuria, gingival bleeding, and hematochezia. Standardized scoring systems may be helpful to estimate the likelihood of HIT. The 4T score can be utilized to evaluate the following potential indicators of HIT: (1) relative platelet count fall, (2) timing of the onset of the platelet count fall, (3) presence or absence of thrombosis, or (4) likelihood of another cause. Each indicator is scored on a scale of 0 to +2. The higher the resultant score, the higher the likelihood of having HIT.[22]

Differentiating between decreased platelet production, increased platelet destruction, splenic sequestration of platelets and hemodilution as well as a review of a blood smear can help the clinician rule in or exclude various possible causes of thrombocytopenia. An abrupt decrease in platelet count usually signifies an acute destructive process via immune or nonimmune processes. Decreased megakaryocytes on bone-marrow biopsy and pancytopenia are indicative of thrombocytopenia due to decreased production. Splenomegaly can lead to thrombocytopenia secondary to platelet redistribution in splenic vascular beds. Hemodilution may result from the administration of crystalloids, colloids, or even platelet-deprived blood products and can result in a relative thrombocytopenia. In addition to drugs, one must consider many nondrug causes of thrombocytopenia in the differential diagnosis (**Table 46-4**).

Table 46-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Thrombocytopenia[22,34,52]

- Acute lymphoid leukemia
- Acute myeloid leukemia
- Alcohol consumption
- Antineoplastic chemotherapy
- Aplastic anemia
- Chronic hepatic failure
- Chronic leukemia
- Disrupted hematopoiesis
- Disseminated intravascular coagulation
- Exposure to blood products
- Hepatic disease
- Human immunodeficiency virus
- Immune (idiopathic) thrombocytopenic purpura
- Insertion of pulmonary artery catheter

- Lymphomas
- Metastatic cancer
- Myelodysplastic syndromes
- Myeloproliferative neoplasia
- Myeloproliferative syndromes
- Pregnancy
- Prosthetic valves
- Pseudothrombocytopenia (platelet clumping)
- Sepsis
- Splenomegaly
- Thrombotic thrombocytopenic purpura
- Vasculitis

Ethylenediamine tetra-acetic acid, an in vitro calcium-chelating anticoagulant used for laboratory processing, reacts with GPIIb/IIIa-reactive autoantibodies and can cause an electronic particle counter to falsely read blood samples as thrombocytopenia.[46] This pseudothrombocytopenia is estimated to occur in approximately 0.1% of analyzed blood samples and can be avoided by using sodium citrate or heparin anticoagulant-treated collection tubes.

With HIT, platelet counts rarely decrease to <10,000/mm^3.[47] Onset of thrombocytopenia in a patient not previously exposed to heparin typically occurs after 5–10 days of exposure as compared with hours for previously exposed patients.[48] HIT, unlike other drug-induced thrombocytopenias, carries a risk of venous thromboembolism rather than petechiae and hemorrhage.[21,22,49] In addition, low-molecular-weight heparins (LMWHs) such as enoxaparin and dalteparin can be responsible for HIT. Although anecdotal case reports exist, fondaparinux, which binds directly to antithrombin, is considered to have a low potential for HIT.[22,50,51]

Heparin is considered one of the most thrombogenic drugs, and patients may present with upper-extremity deep-vein thrombosis, lower-extremity deep-vein thrombosis, or a pulmonary embolism.[48] Patients may also present with heparin-induced skin necrosis, gangrene, or anaphylaxis.[21,22]

A careful medical and medication history should be obtained for patients presenting with thrombocytopenia. The medication history should include details regarding recent medication changes and use of complementary and alternative medicines. The laboratory evaluation of patients with suspected drug-induced thrombocytopenia may include GP-specific platelet antibody assays and an evaluation of drug-dependent increases in platelet-associated IgG.[52] Specifically for HIT, C-serotonin platelet release assay, PF4/heparin enzyme-linked immunosorbent assay (ELISA), or both may be used, with a positive predictive value of 89–100% and 10–93%, respectively.[21,52] The negative predictive value of a serotonin assay and ELISA are approximately 80% and 95%, respectively.[21]

RISK FACTORS

Drug-induced thrombocytopenia is a rare event, and general risk factors other than recent drug exposure are unknown. With cyclosporine, tacrolimus, sirolimus, and valproic acid, there appears to be a relationship between higher serum concentrations and a risk for thrombocytopenia.[36,43] With valproic acid, a daily dose exceeding 1,000 mg, concurrent use of aspirin, and advanced age appear to confer higher risk.[53] Therapy with linezolid for >2 weeks has been associated with drug-induced thrombocytopenia.[54] Past use of heparin and LMWHs (especially within the past 100 days) places individuals at an increased risk for drug-induced thrombocytopenia (**Table 46-5**).[22,48,52,55]

Table 46-5 Risk Factors for Drug-Induced Thrombocytopenia

Heparin, low-molecular-weight heparins[22,48,52,55]

- History of heparin-induced thrombocytopenia
- Previous exposure to heparin or low-molecular-weight heparin (especially within the past 100 days)

Valproic acid[53]

- Advanced age
- Concurrent use of aspirin
- High-serum valproic acid concentrations

Linezolid[54]

- >2 weeks of treatment

MORBIDITY AND MORTALITY

A review by George and colleagues suggests that patients presenting with definite or probable drug-induced thrombocytopenia (nonheparin-related) have a 9% risk of major bleeding and an associated mortality rate of 0.8%.[4,5] HIT may occur in 1–3% of patients receiving treatment, and the typical onset is 5–14 days. HIT is associated with a 50% cumulative risk of thrombosis over 30 days.[55] Venous thrombotic events are more common than arterial events in HIT, and practitioners must recognize that pulmonary embolism may be more prevalent than deep-vein thrombosis, with risk persisting even weeks after platelet recovery.[21,55]

Thrombotic thrombocytopenic purpura is associated with cerebral and myocardial infarctions and renal failure, resulting in a mortality rate of 90% in patients not receiving treatment.[35,36] It is estimated that plasma exchange in quinine-induced TTP has increased survival from 25% without treatment to 100% with treatment.[44] However, neurologic sequelae and chronic renal failure may persist despite treatment and cessation of quinine therapy.[40]

PREVENTION

Many commonly prescribed drugs can cause thrombocytopenia and, given the unpredictable nature of this drug-induced disease, prevention is challenging. In contrast to most drugs, thrombocytopenia secondary to many of the chemotherapy agents is predictable, and clinicians can often make dosing adjustments to help minimize this effect (**Table 46-6**). For patients who experience severe chemotherapy-associated thrombocytopenia, oprelvekin can be used.[56,57] Oprelvekin promotes growth and maturation of megakaryocytes. The adult dose is 50 mcg/kg/day given subcutaneously for 10–21 days after chemotherapy. Treatment should be started at least 24 hours after chemotherapy and should be discontinued at least 48 hours before the next cycle. Oprelvekin is associated with significant toxicity. Many of the side effects mimic capillary-leak syndrome, with patients having fluid retention, dyspnea, tachycardia, atrial arrhythmias, syncope, headache, fever, nausea, anemia, arthralgias, myalgias, and pleural effusions. Clinicians must weigh the risk of these adverse effects against the benefits of treatment.

Routine monitoring of platelet counts is necessary for many patients who receive unfractionated heparin or LMWH, and the American College of Chest Physicians has published recommendations to help guide clinicians.[21,58] For patients who are starting unfractionated heparin or LMWH treatment and who have received unfractionated heparin within the past 100 days, or for those in whom exposure history is uncertain, a baseline platelet count and then a repeat platelet count within 24 hours of starting heparin is recommended. For patients who are receiving therapeutic dose unfractionated heparin, platelet count monitoring at least every 2–3 days from days 4–14 (or until heparin is stopped, whichever occurs first) is recommended.

Table 46-6 Early Detection and Prevention of Drug-Induced Thrombocytopenia[58]

For patients starting unfractionated heparin or LMWH
(if exposed to heparin in the past 100 days or if exposure history is uncertain)

- Baseline platelet count
- Platelet count within 24 hours

For patients receiving therapeutic-dose unfractionated heparin

- Baseline platelet count
- Platelet count at least every 2–3 days on days 4–14 of therapy
- Monitoring can be stopped at discontinuation of heparin therapy or after 14 days of therapy (whichever comes first)

For patients receiving postoperative antithrombotic prophylaxis with unfractionated heparin

- Every-other-day platelet count monitoring on postoperative days 4–14
- Monitoring can be stopped at discontinuation of heparin therapy or after 14 days of therapy (whichever comes first)

For medical or obstetrical patients receiving prophylactic-dose unfractionated heparin or LMWH after first receiving unfractionated heparin; for postoperative patients receiving prophylactic-dose LMWH or intravascular catheter unfractionated heparin "flushes"

- Platelet count monitoring at least every 2–3 days on days 4–14
- Monitoring can be stopped at discontinuation of heparin therapy or after 14 days of therapy (whichever comes first)

For detection of chemotherapy-related thrombocytopenia

- Platelet count prior to initial chemotherapy
- Platelet count prior to next cycle
- If complications occur, check the platelet count

LMWH = low-molecular-weight heparin.

Patients who are receiving postoperative antithrombotic prophylaxis with unfractionated heparin are at highest risk for HIT. In these patients, every-other-day platelet count monitoring between postoperative days 4 and 14 (or until unfractionated heparin is stopped, whichever occurs first) is recommended. Specific recommendations regarding monitoring of individual fibrinogen inhibitors/GPIIb/IIIa are also available.[30]

Medical or obstetrical patients who are receiving prophylactic-dose unfractionated heparin, postoperative patients receiving prophylactic-dose LMWH, postoperative patients receiving intravascular catheter unfractionated heparin "flushes," or medical or obstetrical patients receiving LMWH after first receiving unfractionated heparin are at relatively low risk for HIT. In these patients, platelet count monitoring at least every 2–3 days from day 4 to day 14 (or until heparin is stopped, whichever occurs first), when practical, is recommended.

HIT is rare in medical and obstetrical patients who are receiving only LMWH, and medical patients who are receiving only intravascular catheter unfractionated heparin flushes. In these patients, routine platelet count monitoring is not recommended.

MANAGEMENT

The most obvious primary treatment for drug-induced thrombocytopenia is discontinuation of the offending agent. In most cases, the platelet count returns to pretreatment levels relatively quickly, with a median time to platelet recovery of approximately 7 days (range of 1–30 days).[4] In patients with HIT, management must include the removal of all sources of heparin, including heparin flushes. The ultimate goal of therapy for patients with HIT is to prevent thrombosis, because these patients have a 30-fold increased risk of suffering a thrombotic event. Management includes decreasing both platelet activation and thrombin generation, and this is typically accomplished by using alternative anticoagulation therapy such as a direct thrombin inhibitor.[59]

Warfarin and other anticoagulants (e.g., LMWH) should not be prescribed in patients with HIT. Individuals receiving LMWH have a high cross reactivity with PF4 heparin antibodies.[22,58] Patients with HIT who are treated with warfarin usually develop an international normalized ratio >4. This occurs because of the reduction of protein C and persistent thrombin generation. Once thrombin generation is controlled with a direct thrombin inhibitor and thrombocytopenia has resolved (i.e., platelets >150,000/mm^3), warfarin can be given safely. If HIT is not resolved before initiating warfarin, fulminant venous limb gangrene can occur.[22,52,60,61]

Two drug classes available for the treatment of HIT are the direct thrombin inhibitors and heparinoids. Direct thrombin inhibitors include lepirudin, bivalirudin, and argatroban. Danaparoid is a representative heparinoid. These agents directly bind to and inactivate thrombin and do not require antithrombin.[21] There is no cross-reactivity between heparin and the direct thrombin inhibitors and all of the products have short half-lives (25–80 minutes).[22,52]

Lepirudin is a recombinant hirudin derivative (i.e., leech protein). It is approved by the FDA for use in the treatment of HIT and associated thromboembolic diseases to prevent further thromboembolic complications. This agent is metabolized by the kidneys and its use should be avoided in patients with renal failure. Although current recommendations suggest that an initial bolus dose is not necessary, in life-threatening situations a bolus dose of 0.2 mg/kg may be used. The highest infusion rate recommended during initiation of therapy is 0.10 mg/kg. The target activated partial thromboplastin time (aPTT) is 1.5–2 times baseline. The aPTT should be checked every 4 hours initially and then less often once steady state has been achieved.[22,58]

Studies have demonstrated reduction in composite end points (i.e., new thrombosis, limb amputation, and mortality from all causes) when lepirudin was used.[62,63] In an analysis of three of these studies, the incidence of death, amputation, and thrombosis was decreased to 20.3% in patients treated with lepirudin from

43% in controls.[64] Patients treated with lepirudin experienced more bleeding (17.6% versus 5.8% in the control group). There have been reports of the development of antibodies to lepirudin with repeated exposure and after the administration of even a single bolus dose. Antibody formation has been associated with fatal anaphylactic reactions; therefore, lepirudin should not be used more than once in a given patient.[64]

Bivalirudin, a synthetic thrombin inhibitor modeled after hirudin, is approved for use in per-cutaneous coronary intervention in patients who have or are at risk for HIT. The half-life is shorter than that of lepirudin (25 minutes versus 80 minutes) and it undergoes enzymatic metabolism, so only minor dose adjustments are needed in patients with renal insufficiency.[21,22,52] No bolus administration is required for use in HIT, and initial infusion rates range from 0.15 to 0.2 mg/kg/hr. If a patient has renal dysfunction, the infusion rate should be reduced from 0.03 to 0.1 mg/kg/hr.[65] The aPTT should be monitored, with target values 1.5–2.5 times baseline.

Argatroban is also a direct thrombin inhibitor that binds reversibly to thrombin. It is approved for use in the treatment and prevention of thrombosis in HIT. No bolus dose is needed, and the initial infusion rate is 2 mcg/kg/min. To achieve target aPTT levels, doses can range from 0.5 to 2 mcg/kg/min. Unlike the other direct thrombin inhibitors, argatroban is metabolized by the liver. In patients with moderate hepatic impairment (Child-Pugh score of 7–11), the dose should be reduced to 0.5 mcg/kg/min. The drug should not be used at all in patients who have alanine aminotransferase or aspartate aminotransferase values >3 times the upper limit of normal.[66-68] A baseline aPTT should be determined and values then monitored to maintain an aPTT of 1.5–3 times the baseline. The incidence of composite end points (death, amputation, thrombosis) has been reported to decrease from 43% in controls to 35% with argatroban treatment, and the major improvement noted was a significant decrease in the risk of thrombotic events (10–14% with argatroban versus 25% in controls).[22,67,68]

Danaparoid, which is classified as a heparinoid, represents another class of drugs used for the treatment of HIT. This agent works by inhibiting the activation of factor X via antithrombin. It is the only agent that has compared favorably with direct thrombin inhibitors; however, it is not currently available for use in the United States.

Direct-acting oral anticoagulants are approved for various indications, including nonvalvular atrial fibrillation, deep-vein thrombosis, pulmonary embolism, and postoperative venous thromboprophylaxis. With regard to HIT, data are limited to case reports and case series, and there is insufficient clinical experience to recommend them as a treatment option.[69]

Thrombocytopenia is a well-known adverse effect associated with cancer chemotherapy. Depending on the chemotherapy regimen and the number of previous chemotherapy cycles, platelet counts typically return to normal over time. In certain situations, however, a decision to administer a platelet transfusion may be warranted. This decision is based on the presence or absence of bleeding and a patient's platelet count. Guidelines have been established to help clinicians decide when to administer platelet transfusions and when it is appropriate to wait.[70,71] Based on guidelines published by the American Society of Clinical Oncology, a platelet transfusion is recommended for patients with no evidence of active bleeding when the platelet count decreases to <10,000/mm^3. Data derived from patients with leukemia who have chemotherapy-induced thrombocytopenia showed that this approach conserved healthcare resources and did not place the patient at increased risk for bleeding.[70] There are situations in which a platelet transfusion is recommended despite a platelet count >10,000 mm^3, including cancers associated with necrotic tumors such as gynecologic, colorectal, and bladder cancers, as well as melanoma. Patients who are to undergo surgery should have platelet counts of at least 40,000–50,000/mm^3 to ensure safety.[71] The use of platelet transfusions in patients with HIT is not recommended.[58]

Although these various recommendations have been established to help guide clinicians in the appropriate use of platelet transfusions, patients should be evaluated on a case-by-case basis. Platelet transfusions are not without risk, and patients can experience fever, allergic reactions, alloimmunization, and infection.[70]

Steroids and high-dose intravenous immunoglobulin have also been used to treat drug-induced thrombocytopenia, although their utility and benefit have not been clearly demonstrated.[72] Different steroid agents and dose ranges have been suggested. Prednisolone 15–160 mg daily, methylprednisolone 1 mg/kg every 8 hours, or oral prednisone up to 1 mg/kg/day have been used.[1,72] It is often difficult to differentiate between ITP and drug-induced thrombocytopenia. Because corticosteroids have proven beneficial in the treatment of ITP, these agents should be used when ITP is suspected and at least until ITP can be ruled out.[3] Similarly, intravenous immunoglobulin in a dose of 1 g/kg/day for 2 consecutive days, may be considered in patients in whom ITP is suspected.[73] Thrombopoietin mimetics, such as romiplostim or eltrombopag, which regulate megakaryocyte and platelet production, have been studied for use in patients with thrombocytopenia. However, benefit of use specifically in drug-induced thrombocytopenia is not established. These agents are FDA-labeled for chronic immune-mediated thrombocytopenia.

INFORMATION FOR PATIENTS

Patients should be adequately counseled when prescribed any agent that could potentially induce thrombocytopenia. Education should include signs and symptoms of bleeding, including unusual bruising, heavy or prolonged menses, prolonged bleeding of the gums after brushing or flossing, or even prolonged bleeding from a minor cut. Patients should be advised to contact their healthcare provider immediately if any of these occur. Once a drug-induced thrombocytopenia has been diagnosed, it is important to ensure that this information is added to the patient's medical records to help prevent recurrent events.

CHAPTER 47

Thromboembolic Diseases

Candice L. Garwood

Thromboembolic disease is one of the most common cardiovascular disorders, characterized by blood clot formation known as thrombosis. Although thrombosis may occur almost anywhere within the vascular system, the most common presentation involves deep vein thrombosis (DVT), which develops in the venous circulation, with the possible complication of pulmonary embolism (PE). DVT and PE are distinct but related manifestations of the same disease process known as venous thromboembolism (VTE). Typically, DVT develops within the large deep veins of the calf. About 10–20% of distal DVT extend proximally. DVT may also develop elsewhere, such as the upper extremity, mesenteric, renal, or cerebral veins. About 1–5% of thrombi are dislodged, travelling through the vasculature, also known as an embolus. The most common site for emboli to lodge is a vessel of the lung, forming a PE. VTE can be provoked by immobility, trauma, or may result from drug or disease factors. However, VTE may also be idiopathic, without a specific known predisposing factor. In general, development of VTE is multifactorial, making it difficult to identify a primary cause.[1] This chapter will focus on drug-induced thromboembolic disease.

CAUSATIVE AGENTS

Table 47-1 lists agents, grouped by drug class, that have been reported to cause thromboembolism.[2-227] Drugs that interact with and reduce the effectiveness of anticoagulants are not included if they have not been directly associated with thromboembolic development (e.g., rifampin inducing the metabolism of warfarin).

EPIDEMIOLOGY

The overall incidence of drug-induced thromboembolism is unknown because of the multifactorial pathogenesis of this disease. Furthermore many patients have clinically silent disease or go undiagnosed.[228] The incidence and level of supportive evidence associated with some specific drugs are reported in Table 47-1. When examining the rate of objectively diagnosed VTE, the annual incidence is estimated at 2–3/1,000. The rate of VTE increases with advancing age, such that the incidence doubles each decade of life after age 50 years, reaching a rate of 8/1,000 in those over 80 years. With an aging population, it is expected that the incidence of DVT and PE will rise.[229]

Table 47-1 Agents Implicated in Drug-Induced Thromboembolic Diseases Agents Implicated in Drug-Induced Thromboembolic Diseases

Drug	Incidence	Level of Evidence[a]
HEMOSTATIC AGENTS		
Aminocaproic acid[2-5]	NK	C
Aprotinin[6-9]	1%	B
Cyanoacrylate[10-12]	NK	C
Desmopressin[13,14]	NK	C
Eptifibitide[15,16]	NK	C
Protamine sulfate[17]	NK	B
Activated prothrombin complex concentrate[18]	NK	B
3-factor prothrombin complex concentrate[19]	0.7%	B
4-factor prothrombin complex concentrate[19]	1.8%	B
Recombinant factor VIIa[20-23]	7–9.4%	A

Tranexamic acid[24,25]	NK	C
ANTICOAGULANTS		
Heparin[26-30]	1–5% develop HIT, 25–50% of those develop HITT	B[a]
Low-molecular-weight heparin[26,27]	2.2%	B[a]
Pentosan[31-33]	NK	B
Streptokinase[34-36]	NK	C
Urokinase[37]	NK	C
Warfarin (coumarin derivatives)[38-40]	NK	B
HEMATOPOIETIC AGENTS		
Darbepoetin[41-45]	3.3–8%	A
Erythropoietin[43-48]	3.3–26.7%	A
G-CSF[49,50]	NK	B
GM-CSF[49,51]	NK	B
ESTROGEN-CONTAINING AGENTS		
Diethylstilbestrol[52,53]	6.8–7%	A
Oral contraceptives[54-58]	6 times the risk of nonusers; 1–2/10,000 woman-year	A
Hormone replacement[57,59-61]	0.2–5.9/100 woman-year	A
ANTIANDROGENS		
Cyproterone[62-64]	5.23 increased odds	B
Flutamide[65]	5%	B[a]
Goserelin[66]	1–5%	B
Leuprolide[67-69]	16.7%	A
SELECTIVE ESTROGEN-RECEPTOR MODULATORS		
Raloxifene[57,70]	9.5/100 woman-year	A
Tamoxifene[57,71-74]	3.6–12/100 woman-year	A
Toremifene[75]	1.5%	B
AROMATASE INHIBITORS		
Anastrozole[76-79]	1–2.2%	A
Letrazole[80]	NK	C
ANDROGENIC AGENTS		
Danazol[81,82]	NK	C
	NK	C

Nandrolone[83,84]		
Megestrol[85,86]	4.9%	B[a]
FOLLICLE-STIMULATING HORMONE		
Follitropin alfa[87-89]	NK	C
ANTINEOPLASTIC AGENTS		
Aldsleukin[90,91]	<1%	B
Asparaginase[92-96]	11–36.7%	A
Basiliximab[97]	3–10%	B
Bevicizumab[98-100]	4.4–5%	A
Bleomycin[101,102]	NK	B
Carboplatin[103,104]	NK	B
Cisplatin[101,102,105-108,112,113]	0.67%	B
Dacarbazine[109,110]	NK	C
Denileukin[111]	11%	B[a]
Docetaxel[114-116]	8.8%	A
Estramustine[116-120]	0 ≥20%	A
Etoposide[102,120]	NK	A
Fluorouracil[121-123]	NK	B
Gemcitabine[112]		
Imatinib[116,124,125]	NK	B
Irinotecan[100,126]	12.5%	B
Lenalidomide[127-131]	8%	A
Paclitaxel[120,132-134]	NK	B
Ponatinib[135,136]	NK	A
Ranibizumab[137,138]	NK	B
Rituximab[139]	NK	B
Soraftnanib[140]	NK	B
Thalidomide[43,130,131,141-146]	3.4–26%	A
IMMUNOLOGIC AGENTS		
Cyclosporine[147-151]	NK	B
Dexamethasone[93,142,152]	NK	A
Foscarnet[153]	NK	C

Infliximab[154-156]	NK	B
Immunoglobins[157-161]	3–3.8%	A
Interferon gamma[162,163]	NK	B
Interferon alfa-2a[164,165]	NK	B
Interferon alfa-2b[166-168]	NK	C
Interferon beta[169,170]	NK	C
Interleukin-3[171]	NK	C
Methylprednisolone[172]	NK	B
Muromonab[150,172,173]	<1%	B[a]
Prednisone[93,152,174]	NK	A
Sirolimus[175,176]	NK	B
Tacrolimus[147-149,151]	NK	B
ANTIPSYCHOTIC AGENTS		
Chlorpromazine[177-181]	NK	B
Clozapine[182,183]	1.35%	B
Olanzapine[182,184,185]	1.17%	B
Quetiapine[182]	1.35%	B
Risperidone[177,182]	1.25%	B
Thioridazine[181,186]	NK	B
OTHER PSYCHOTROPIC AGENTS		
Clomipramine[187]	NK	C
Escitalopram[188]	NK	C
Lithium[189-191]	NK	C
CONTRAST AGENTS		
Iohexol[192-194]	22.2%	B
Iomeprol[195]	0.8–4.2%	B[a]
Iopamidol[196]	9–22.2%	B[a]
Iothalamate[197,198]	8–28.6%	B
Ioxaglate[192,193,195,196,199]	2.7–4.8%	B[a]
MISCELLANEOUS		
Acetohydroxamic acid[200]	NK	B
Botulinin toxin[202,203]	NK	C
	NK	C

Bromocriptine[203-205]		
Calcium gluconate[206]	NK	C
Cocaine[207-209]	NK	C
Dihydroergotamine[210-212]	NK	C
Ecstasy (3,4-methylenedioxymethamphetamine; MDMA)[213,214]	NK	C
Ergotamine[210,215-217]	NK	C
Metolazone[218]	NK	C
Papaverine[219]	NK	B
Procainamide[220,221]	NK	C
Sildenafil[222-224]	NK	C
Topiramate[225]	6.1%	A
Tretinoin[226,227]	NK	B

G-CSF = granulocyte colony-stimulating factor, GM-CSF = granulocyte /macrophage colony-stimulating factor, HIT = heparin-induced thrombocytopenia, HITT = heparin-induced thrombocytopenia and thrombosis, NK = not known.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials;

Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

Oral contraceptives are perhaps the best-recognized class of agents known to cause VTE. A meta-analysis of 26 studies identified a 3.5-fold increased relative risk of VTE with use of oral contraceptives compared with nonuse. The relative risk of VTE for combined oral contraceptives with 30–35 mcg ethinyl estradiol and either a third- or fourth-generation progestin (gestodene, desogestrel, cyproterone acetate, or drospirenone) were about 50–80% higher than for combined oral contraceptives with levonorgestrel, with higher doses associated with higher thrombosis risk.[230] However, other reports raise questions about the increased thromboembolic risk associated with newer generation progestins.[231,232] The reported incidence of VTE with other drugs varies widely, from <1% in patients receiving the antineoplastic agent aldesleukin and up to 26% in patients treated with thalidomide.[90,91,130]

MECHANISMS

Hemostasis is dependent on a delicate balance in the complex relationship between thrombogenic and antithrombotic factors. A disruption in this equilibrium may lead to inappropriate clot formation and the possibility of embolization to a distant vascular bed. Any circumstance resulting in venous stasis, vascular injury, or hypercoagulability, factors known as Virchow's triad, may lead to VTE.[233-236] Venous stasis occurs with a slowed rate of blood flow. The most common site for venostasis is the large venous sinuses of the thigh or calf, where pooling of blood can be precipitated by periods of physical immobility such as bed rest and air travel. Vascular injury can be a result of trauma or surgical procedures. In addition, vascular injury may be caused by pooling of blood that causes distention of the vessel where resultant damage to the endothelium can activate the coagulation system.[237]

Hypercoagulability is the result of an inherited defect or the presence of an acquired, often transient, risk factor such as a drug. Although venous thromboemboli generally originate in the lower-extremity venous pathways, they may also occur in other regions, such as renal veins, pelvic veins, upper-extremity veins, or the cerebral venous sinuses.[233] The most common location for embolization to occur is the lung.[233] The proposed mechanisms for agents known to cause VTE are described in **Table 47-2**.[5, 9-11, 13, 14, 17, 23, 24, 32, 34, 49, 50, 57, 58, 92, 106, 107, 114, 122, 125, 130, 135, 145, 151, 165, 167, 170, 178, 188, 189, 200, 210, 215, 222, 226, 227, 238-266]

Hemostatic agents that inhibit fibrinolysis may prevent the lysing of previously formed clots and predispose patients to VTE. Drugs including aminocaproic acid, aprotinin, desmopressin, and tranexamic acid have been associated with VTE, likely via this mechanism.[2-9,13,14,24,25] Other drugs, including antipsychotic agents and contrast media can create a hypercoagulable state through platelet activation and aggregation that can lead to VTE.[177,179,181,182,192,195-197,199] Some studies suggest that ionic contrast media (e.g., iothalamate, ioxaglate) are less thrombogenic than the nonionic forms (e.g., iopamidol).[196]

Although uncommon, anticoagulation therapy itself may cause VTE by creating a hypercoagulable state. Warfarin can cause thrombosis in the microvasculature, which is known as skin necrosis. This appears to be caused by the drug's early inhibition of vitamin K–dependent anticoagulant proteins C and S and a slower onset of the complete inhibition of vitamin K–mediated clotting factors necessary for warfarin's full anticoagulation effect. The potential for warfarin-induced hypercoagulability is primarily associated with a known protein C deficiency. Hypercoagulability has been reported less commonly with protein S deficiency and also can occur in nondeficient individuals.[242] For this reason, it is prudent to begin heparin therapy prior to or concurrent with the start of warfarin in patients with acute VTE who will be anticoagulated with warfarin.[242,267,268] Heparin can cause thrombosis by inducing formation of antibodies in a syndrome known as heparin-induced thrombocytopenia (HIT). Low-molecular-weight heparins (LMWHs) have also been reported to cause HIT, but at a much lower rate than heparin.[241] Pentosan, a heparin analog, also has the ability to induce antibodies causing thrombosis.[31,32]

Hormonal and other agents that affect the endocrine system exhibit a diverse spectrum of mechanisms for inducing thromboembolic disease. Estrogen-containing agents increase factor II, VII, VIII, and fibrinogen levels. There are reductions in natural anticoagulants, antithrombin III, and protein S. In addition, estrogens are known to cause resistance to activated protein C. This is especially problematic in patients with factor V Leiden mutation, as these patients possess an inherited resistance to activated protein C. The cumulative effect of estrogen's induced hypercoagulability can lead to thrombosis.[57,230] The antiandrogens may increase platelet aggregation and alter the fibrinolytic system. Finally, selective estrogen-receptor modulators are thought to reduce the concentrations of antithrombin, protein C, and protein S, causing venous thrombosis.[57]

Table 47-2 Mechanisms of Drug-Induced Thromboembolic Diseases

Drug	Mechanism
HEMOSTATIC AGENTS	
Aminocaproic acid[5]	Inhibits fibrinolysis
Aprotinin[9]	High doses inhibit kallikrein and protein C; inhibits fibrinolysis
Cyanoacrylate[10,11,238]	Endothelial damage, embolization
Desmopressin[13,14]	Increases plasminogen-activator activity; inhibits fibrinolysis
Eptifibitide[15,16]	Induced thrombocytopenia and disseminated intravascular coagulation
Protamine sulfate[17]	Platelet-activating, anti-protamine-heparin antibodies
Activate prothrombin complex concentrate[239]	Concentrated active clotting factor repletion
3-factor prothrombin complex concentrate[239]	Concentrated clotting factor repletion
4-factor prothrombin complex concentrate[239]	Concentrated clotting factor repletion
Tranexamic acid[24,240]	Inhibits fibrinolysis
Recombinant factor VIIa[23,239]	Increased clotting-factor activity; dose-related
ANTICOAGULANTS	
Heparin/low-molecular-weight heparin[241]	Platelet activation secondary to antibody formation
Pentosan[32,33]	Platelet aggregation; heparin analog with potential to cause HIT
Streptokinase[34]	Antibody-induced platelet aggregation
Urokinase	NK
Warfarin (coumarin derivatives)[242]	Inhibits proteins C and S activity, potential for

	temporary hypercoagulability
HEMATOPOIETIC AGENTS	
Darbepoetin[243]	Increases endothelial-cell activity and increases platelet reactivity; dose-related
Erythropoietin[243]	Increases endothelial cell activity and platelet reactivity; dose-related
G-CSF[49,50]	Uncertain; increases platelet adhesion, fibrinogen, and clotting factors; decreases proteins C and S activity
GM-CSF[49,50]	Uncertain; increases platelet adhesion; increases fibrinogen and clotting factors; decreases proteins C and S activity
ESTROGEN-CONTAINING AGENTS	
Diethylstilbestrol	NK
Oral contraceptives[57,58]	Acquired resistance to activated protein C
Hormone replacement[57]	Acquired resistance to activated protein C
ANTIANDROGENS	
Cyproterone	NK
Flutamide	NK
Goserelin	NK
Leuprolide	NK
SELECTIVE ESTROGEN-RECEPTOR MODULATORS	
Raloxifene[57]	Uncertain; decreases antithrombin III, proteins C and S
Tamoxifen[57]	Uncertain; decreases antithrombin III, proteins C and S
Toremifene[57]	Uncertain; decreases antithrombin III, proteins C and S
AROMATASE INHIBITORS	
Anastrozole	NK
Letrazole	NK
ANDROGENIC AGENTS	
Danazol	NK
Nandrolone	NK
Megestrol[244]	Increases prothrombin, fibrin, and plasmin–antiplasmin complex
FOLLICLE-STIMULATING HORMONE	
Follitropin alfa[245]	Ovarian hyperstimulation syndrome leading to elevated estrogen concentrations and hypercoagulability
ANTINEOPLASTIC AGENTS	
Aldesleukin[246]	Induces antiphospholipid antibodies
Asparaginase[92,247]	Hyperfibrinogenemia Decreases anti-plasmin and plasminogen

	concentrations and increases thrombin
Basiliximab248	Uncertain; endothelial-cell apoptosis and dysfunction
Bevacizumab248,249	Uncertain; endothelial-cell apoptosis and dysfunction
Bleomycin250	Uncertain; thrombotic microangiopathy
Carboplatin251	Increase procoagulant activity via isomerase decryption of tissue factor
Cisplatin106,107,251	Endothelial damage, platelet aggregation; increase procoagulant activity via isomerase decryption of tissue factor; possible increase vonWillebrand factor.
Dacarbazine	NK
Denileukin	NK
Docetaxel114	Uncertain; up regulation of thrombomodulin
Estramustine252	Uncertain; estrogenic component may cause acquired resistance to activated protein C
Fluorouracil122,253,254	Left ventricular dyskinesia leading to apical thrombus; disruption of folate synthesis leading to hyperhomocysteinemia; vascular injury
Gemcitibine251	Increase procoagulant activity via isomerase decryption of tissue factor
Imatinib125	Induces thrombotic thrombocytopenic purpura
Irinotecan	NK
Lenalidomide 130	Uncertain; platelet hyperactivity
Paclitaxel251	Increase procoagulant activity via isomerase decryption of tissue factor
Ponitanib135	Platelet activation; increased platelet aggregation
Ranibizumab249	Uncertain; endothelial-cell apoptosis and dysfunction
Rituximab	NK
Soraftanib249	Uncertain; endothelial-cell apoptosis and dysfunction
Thalidomide130,145	Uncertain; platelet hyperactivity; activated protein C resistance
IMMUNOLOGIC AGENTS	
Cyclosporine151	Increases factor VIII, fibrinogen, and von Willebrand factor
Dexamethasone255	Decreases fibrinolysis due to inhibitory effects of PAI-1 on plasminogen activator; increases p-selectin and von Willebrand factor
Foscarnet	NK
Infliximab256	Induces antibodies, including antiphospholipid antibodies
Immunoglobulins257	Red cell aggregation; dose-related
	Modulates fibrinolytic effect of endothelial cells;

Interferon gamma[258]	increases plasma-activated complement
Interferon alfa-2a[165]	Procoagulant antibodies; increases plasma-activated complement
Interferon alfa-2b[167]	Procoagulant antibodies; increases plasma-activated complement
Interferon beta[170]	Procoagulant antibodies; increases plasma-activated complement
Interleukin-3	NK
Methylprednisolone[255]	Decreases fibrinolysis due to inhibitory effects of PAI-1 on plasminogen activator; increased p-selectin and von Willebrand factor
Muromonab[259,260]	Increases platelet activity and endothelial activity
Prednisone[255]	Decreases fibrinolysis due to inhibitory effects of PAI-1 on plasminogen activator; increases p-selectin and von Willebrand factor
Sirolimus[261]	Vascular endothelial growth factor upregulation resulting in disruption of vessel network
Tacrolimus [261]	Vascular endothelial growth factor upregulation resulting in disruption of vessel network
ANTIPSYCHOTIC AGENTS	
Chlorpromazine[178]	Hyperprolactinemia-increased platelet activity; induces anticardiolipin antibodies
Clozapine[262]	Hyperprolactinemia-increased platelet activity
Olanzapine[262]	Hyperprolactinemia-increased platelet activity
Quetiapine[262]	Hyperprolactinemia-increased platelet activity
Risperidone[262]	Hyperprolactinemia-increased platelet activity
Thioridazine[262]	Hyperprolactinemia-increased platelet activity
OTHER PSYCHOTROPIC AGENTS	
Clomipramine[188]	Uncertain; increased serotonin concentrations cause an increase in platelet aggregation
Escitalopram[188]	Uncertain; increased serotonin concentrations cause an increase in platelet aggregation
Lithium[189]	Uncertain; induces dehydration
CONTRAST AGENTS	
Iohexol[263,264]	Platelet aggregation and activation
Iomeprol[263,264]	Platelet aggregation and activation
Iopamidol[263,264]	Platelet aggregation and activation
Iothalamate[263,264]	Platelet aggregation and activation
Ioxaglate[263,264]	Platelet aggregation and activation
MISCELLANEOUS	

Acetohydroxamic acid200	Increases thrombin and platelets
Botulinum toxin	NK
Bromocriptine	NK
Calcium gluconate	NK
Cocaine265	Increases platelet activation
Dihydroergotamine210,215	Uncertain; ergotism, ischemia, venous stasis
Ecstasy (3,4-methylenedioxyethamphetamine; MDMA)	NK
Ergotamine210,215	Uncertain; ergotism, ischemia, venous stasis
Metolazone	NK
Papaverine	NK
Procainamide266	Induces antiphospholipid antibodies
Sildenafil222	Uncertain; decreases blood flow to microcirculation; decreases antithrombin III and protein S
Topiramate	Unknown
Tretinoin226,227	Releases plasminogen activators and lysosomal neutrophil enzymes leading to diffuse intravascular coagulation

G-CSF = granulocyte colony-stimulating factor, GM-CSF = granulocyte/macrophage colony-stimulating factor, HIT = heparin-induced thrombocytopenia, HITT = heparin-induced thrombocytopenia and thrombosis, PAI = plasminogen-activator inhibitor, NK = not known.

Although the mechanism for drug-induced thromboembolism associated with the antineoplastic agents is not precisely known, it is likely that a combination of factors is involved. The drugs themselves may cause hypercoagulability, or drug-induced endothelial damage may occur propagating clot formation. The patient's disease state and the presence of catheters also likely play a role in the development of VTE in patients receiving antineoplastic agents.

Table 47-3 Signs and Symptoms Associated with Drug-Induced Thromboembolic Diseases

Pulmonary embolism

- Accentuated second heart sounds and fourth heart sound
- Cough
- Cyanosis
- Dyspnea
- Hemoptysis
- Hypoxemia (i.e., abnormal arterial blood gases or pulse oximetry)
- Palpitations
- Pleuritic chest pain
- Rales

- Syncope
- Tachycardia
- Tachypnea

Deep vein thrombosis

- Pain or tenderness
- Palpation of a nickel-sized or cord-like obstruction
- Positive Homan's sign
- Skin discoloration (i.e., pallor, cyanosis, or erythema)
- Unilateral warmth, redness, or swelling

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The signs and symptoms of VTE are outlined in **Table 47-3**. There is often a great deal of inter-individual variability in the presenting signs and symptoms of VTE as well as in the time-to-initial presentation. Clinical manifestations of drug-induced VTE are generally not distinct from those of VTE due to any other cause. DVT of the thigh or calf is associated with warmth, redness, and swelling that is generally unilateral. Skin discoloration may also occur, and palpation may reveal a nickel-sized or cord-like obstruction. PE should be suspected whenever a patient has dyspnea without another apparent cause, pleuritic pain, circulatory collapse with no apparent cause, hemoptysis, or syncope.[233] In addition, patients presenting acutely with PE may have sinus tachycardia, gallop rhythm, and elevated jugular venous pressure.

Table 47-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Thromboembolic Diseases

Pulmonary embolism

- Exacerbation of heart failure
- Exacerbation of other pulmonary disease
- Musculoskeletal pain
- Myocardial infarction
- Pneumonia
- Pneumothorax

Deep vein thrombosis

- Baker's cyst
- Cellulitis
- Drug-induced edema
- Knee injury/abnormality
- Leg swelling in a paralyzed limb

- Lymph obstruction
- Muscle strain/tear
- Superficial thrombophlebitis
- Venous insufficiency

Table 47-5 Wells Criteria for Predicting Pretest Probability of Deep-Vein Thrombosis and Pulmonary Embolism[270,271]

Clinical Characteristic	Points
DEEP-VEIN THROMBOSIS[a]	
Active cancer	1
Calf swelling at least 3 cm larger than on the asymptomatic side	1
Collateral superficial veins (nonvaricose)	1
Entire leg swollen	1
Localized tenderness along the distribution of the deep venous system	1
Paralysis, paresis, or recent plaster immobilization of the lower extremities	1
Pitting edema confined to the symptomatic leg	1
Previously documented DVT	1
Recently bedridden for 3 days or more, or major surgery within the previous 12 weeks requiring general or local anesthesia	1
Alternative diagnosis at least as likely as DVT	-2
PULMONARY EMBOLISM[b]	
An alternative diagnosis is less likely than PE	3
Clinical signs and symptoms of DVT	3
Heart rate >100 bpm	1.5
Immobilization or surgery in the previous 4 weeks	1.5
Previous DVT or PE	1.5
Active cancer	1
Hemoptysis	1

DVT = deep-vein thrombosis, PE = pulmonary embolism.

[a] A score ≥2 indicates a high probability of DVT; a score <2 indicates a low probability of DVT.

[b] A score <2 indicates a low probability of PE; a score of 2–6 indicates a moderate probability of PE; and a score >6 indicates a high probability of PE.

The diagnosis of DVT or PE can be challenging, as signs and symptoms are sometimes subtle and nonspecific, and patient presentation can vary substantially. Conditions to consider in the differential diagnoses of DVT include muscular injuries, superficial thromboses, lymphedema, and cellulitis (**Table 47-4**). On physical examination, calf pain resulting from dorsiflexion of the ankle while the knee is in a flexed position (positive Homans sign) is consistent with DVT.[269] The Wells criteria have been created for determining the probability of DVT and PE (**Table 47-5**).[270,271] Each of these criteria has been validated and are commonly used; however, clinical assessment should be used only in conjunction with objective testing.[272] D-dimer is a degradation product of a cross-linked fibrin blood clot. Although the D-dimer test cannot be used to affirmatively diagnose VTE, it has a relatively high negative predictive value, especially in younger patients without associated comorbidity. The American College of Chest Physicians (ACCP) Expert Panel Report makes recommendations about the diagnosis of DVT.[273] In patients found to have a low pretest probability of first extremity DVT or PE as determined by the Wells criteria, a high-sensitivity D-dimer test should be used to rule out VTE. Ultrasonography has high sensitivity and specificity for diagnosis of symptomatic proximal DVT of the lower extremity. Sensitivity of this test decreases, however, in patients who are asymptomatic or have DVT in the calf.[274] Patients with moderate pretest probability are recommended to receive D-dimer testing, proximal compression ultrasonography, or whole leg ultrasound.[273] D-dimer can be used to rule out DVT if a negative ultrasound occurs.[274] Those with high pretest probability are recommended to receive proximal compression or whole leg ultrasonography. Again, D-dimer can be used to rule out a negative result.[274] Contrast venography is the most definitive test for DVT, but it is expensive and requires venous access. For these reasons, lower-extremity ultrasound is preferred.[273]

Conditions to consider in the differential diagnoses of PE include pneumonia, pneumothorax, acute myocardial infarction, and exacerbation of other pulmonary diseases. Patients with PE may have abnormal arterial blood gases and nonspecific electrocardiographic changes. As with DVT, a whole-blood D-dimer assay may be useful to rule out PE in those with low pretest probability using the Wells criteria for PE. However, imaging is essential to diagnose PE in patients with intermediate-to-high pretest probability. Imaging options include a ventilation/perfusion (V/Q) lung scan, helical computed tomography (CT), or multidetector CT angiography. Multidetector CT angiography is most commonly utilized and is the diagnostic test of choice for PE in the United States. It may be used in patients with PE and a positive D-dimer assay result or in those who have a high pretest probability of PE regardless of D-dimer result. In patients with negative CT but high pretest probability, follow-up ultrasound of the lower extremities or pulmonary angiography may be warranted.[274]

RISK FACTORS

Risk factors for drug-induced thromboembolic events do not differ from those for VTE of any other cause. The use of drugs associated with VTE in patients with other risk factors often compounds the risk. **Table 47-6** lists the most important acquired and hereditary risk factors.[233] These risk factors are additive. In some cases, patient risk factors are readily identified or easily calculated using clinical predictive assessment tools.[275,276] A prior history of VTE is perhaps the strongest risk factor for recurrent VTE, presumably because of damage to venous valves and obstruction of blood flow caused by the initial event.[237] Age and sex must both be considered in evaluating relative risk. Women have a higher incidence of VTE during their childbearing years. The incidence of VTE nearly doubles in each decade of life over the age of 50 and is slightly higher in men.[237] Over 80% of patients with VTE have at least one risk factor, whereas many patients possess a combination of factors of Virchow's triad.[234-236]

Table 47-6 Risk Factors for Drug-Induced Thromboembolic Diseases

Acquired

- Age
- Antiphospholipid syndrome
- Heart failure
- Heparin-induced thrombocytopenia
- History of VTE
- Immobilization via institutionalization, long-distance travel, or paralysis
- Indwelling venous catheters
- Inflammatory bowel disease
- Liver disease
- Malignancy
- Myeloproliferative disorders
- Nephrotic syndrome
- Neurologic disease
- Obesity
- Pregnancy/postpartum
- Secondary hyperhomocysteinemia
- Sickle-cell anemia
- Smoking
- Sticky-platelet syndrome
- Superficial vein thrombosis
- Surgery
- Transvenous pacemakers
- Trauma

Hereditary

- Antithrombin deficiency
- Dysfibrinogenemia
- Factor V Leiden/activated protein C resistance gene mutation
- Factor VIII overactivity
- Factor XII deficiency
- Heparin cofactor II deficiency

- Plasminogen activator inhibitor-1 excess
- Primary hyperhomocysteinemia
- Protein C deficiency
- Protein S deficiency
- Prothrombin *20210A* gene mutation

VTE = venous thromboembolism.

Recent surgery imparts a great VTE risk to patients. Orthopedic surgery and trauma surgery confer especially high risks of associated VTE. In addition, there is an increased vulnerability seen in patients who have undergone neurovascular or cardiovascular surgery, renal transplantation, or major surgery for malignancy of the leg, pelvis, abdominal, or thoracic areas.[277-279]

Recent trauma or injury imparts a high risk of VTE. Specifically, there is a high association between DVT and spinal injury, head trauma, and fractures of the pelvis, tibia, and femur. Situations involving prolonged periods of immobilization, such as long-distance travel, total or partial paralysis, and institutionalization (e.g., long-term care facility or hospital) create potential danger for patients because of decreased blood flow in the extremities. The presence of malignancy increases the risk of thromboembolic events. There are several reasons for this, including direct vein compression or invasion by the tumor, increased concentrations of procoagulants such as fibrinogen in the malignant state, and the use of cytotoxic chemotherapy for the treatment of the primary disease.[237]

Varicose veins, obesity, and tobacco smoking are weakly associated VTE risk factors. However, previous DVT or superficial thrombosis are known to increase the odds of developing a new VTE. Other independent risk factors include the presence of central venous catheters or transvenous pacemakers, liver disease, and pregnancy.[237]

MORBIDITY AND MORTALITY

Thromboembolic disease can cause significant morbidity and mortality. Mortality rates can mostly be attributed to PE, in which approximately a quarter of cases present as sudden death.[237] An estimated 2 million people in the United States develop VTE each year, of whom 600,000 are hospitalized and 60,000 die.[280,281] Rate of recurrence following a first episode of VTE is 7.8/100 person-years in 1-year follow-up, and the recurrence rate in the years following is 3/100 person-years.[282] VTE-associated morbidity is most commonly related to development of post-thrombotic syndrome (PTS) in which patients experience pain and chronic swelling, tenderness, skin discoloration, or even skin ulceration long after the initial event. Within 2 years of a symptomatic DVT, PTS will be present in 23–60% of patients and 10% will develop venous ulcers in that time frame. PTS is associated with a high burden of direct and indirect costs. It is estimated that the

U.S. average annual per person costs for someone with PTS is $7,000.[283] Morbidity may also arise from the development of chronic thromboembolic pulmonary hypertension (CTEPH), following PE. Most often CTEPH develops as a result of obstruction of the pulmonary vascular bed due to nonresolving PEs. Despite adequate anticoagulation, CTEPH develops in 1–3.8% of patients within 2 years of a PE.[284,285] Symptoms include shortness of breath, especially on exertion, and fatigue. In severe cases, abdominal and peripheral edema may occur. Without intervention, the prognosis of patients with CTEPH is poor and depends on the severity of pulmonary hypertension. Intervention can be medical or surgical, and costs can be quite high.[286,287] The incidence of morbidity and mortality specifically due to drug-induced VTE is unknown.

PREVENTION

Many VTE risk factors (Table 47-6) are unavoidable. Prevention strategies, therefore, are aimed at minimizing patients' exposure to drugs or combinations of drugs known to increase the risk of VTE (Table 47-1) and closely monitoring patients who have known risk factors. **Table 47-7** provides recommendations for the prevention of drug-induced thromboembolic disease.[94,237,241,242,252,268,288-297]

Patients with a history of VTE or known hypercoagulability should be advised to avoid use of estrogen-containing products, such as oral contraceptives, hormone-replacement therapy, and raloxifene or tamoxifen. In addition, oral contraceptives should be used cautiously in women over 35 years of age and in women of any age who smoke. Whenever possible, oral contraceptives, hormone-replacement therapy, and raloxifene should be discontinued at least 4 weeks (72 hours for raloxifene) prior to surgery. In addition, these agents should be withheld for 2 weeks after surgery and during and after prolonged immobilization.[288,298] Oral contraceptives should be started no earlier than 4–6 weeks after the postpartum period.[288] Patients taking estrogens should ambulate and perform exercises during periods of temporary immobility, such as long car rides or air travel. Estrogen as a component of oral contraceptives should be dosed at 10–35 mcg of ethinyl estradiol per day to minimize thrombosis risk. It is controversial as to whether combined hormonal contraceptives containing desogestrel, gestodene (not available in United States) or drospirenone increase the risk of VTE to a greater extent than products with other progestins. Thus, they should probably be avoided in patients at risk for VTE.[50,231,232,299]

Table 47-7 Approaches to Help Prevent Drug-Induced Thromboembolic Diseases

Oral contraceptives, hormone-replacement therapy[237,288,289,305]

- Ambulate periodically during long episodes of travel or flight
- Estrogen-containing products are contraindicated in patients with acute VTE, history of VTE, or known hypercoagulability
- Discontinue drug 4 weeks in advance of surgery or immobile period; resume 2 weeks after procedure or after mobile
- May use progestin-only pills, medroxyprogesterone, progesterone implant, or IUD in those with history of VTE
- Use gestodene and drosperinone in combination with the lowest dose of ethinyl estradiol (<30 mcg daily) in patients without VTE history

Raloxifene, tamoxifen[291,298]

- Contraindicated in patients with previous VTE or known hypercoagulability
- Discontinue drug at least 72 hours in advance of surgery or immobile period, resume after mobile

Heparin products[241]

- Add heparins to patient allergy list
- Avoid all heparin products in the future
- In patients who develop HIT or HITT or who have a history of HIT or HITT, discontinue heparin products and use alternative anticoagulant acutely and for long-term anticoagulant needs

Warfarin[242,268]

- In patients with skin necrosis, discontinue warfarin and start heparin
- Overlap heparin or LMWH and warfarin for at least 7 days and until INR is ≥2 in those with known protein C or S deficiency or cancer

Erythropoietin, darbopoietin[292,293]

- Adjust dose such that rate of hemoglobin rise does not exceed 1 g/dL over a 2-week period
- Do not initiate treatment if hemoglobin concentration is ≥10 mg/dL
- Maintain hemoglobin concentrations <12 mg/dL in treating patients with anemia
- Use with caution in patients with previous VTE or known hypercoagulability

Thalidomide and lenalidomide[294]

- Patients with multiple myeloma and concurrently receiving chemotherapy and/or dexamethasone should receive prophylactic dose LMWH (enoxaparin 40 mg q 24 hr) or warfarin (INR 2–3), or aspirin 81–325 mg daily, depending on number of VTE risk factors present

Recombinant factor VIIa[295,296]

- Avoid in geriatric patients, those with current or recent VTE, severe atherosclerosis, crush injuries, disseminated intravascular coagulation, or sepsis

Asparaginase[94]

- Consider prophylaxis with LMWH

Estramustine[252]

- Consider use of low-dose warfarin or aspirin 325 mg for prophylaxis

Contrast dye[297]

- Avoid if possible; consider heparin-saline flush after use in venography

DES = diethylstilbestrol, HIT = heparin-induced thrombocytopenia, HITT = heparin-induced thrombocytopenia and thrombosis, IUD = intrauterine device, LMWH = low-molecular-weight heparin, VTE = venous thromboembolism.

Practitioners should complete a careful risk–benefit analysis before prescribing any agent known to induce VTE. This is especially important when the patient has known VTE risk factors. Prophylactic anticoagulation with warfarin, direct oral anticoagulants (DOACs), LMWH, or aspirin is typically not recommended, but may be considered for some patients who require therapy with drugs known to cause VTE or if the patient also has known VTE risk factors. Decisions regarding the use of prophylactic anticoagulation should be made on an individual basis. Risk-factor modification, when possible, should be pursued in all patients.

MANAGEMENT

Anticoagulation is the primary treatment for VTE, whether or not it is drug-induced. Because DVT and PE are manifestations of the same disease process, their treatments are virtually identical. The therapeutic goals are to prevent clot extension and embolization, reduce recurrence, and prevent long-term complications such as PTS.

The ACCP Expert Panel Report set guidelines for the treatment of VTE.[268] Recommended treatment includes the initial administration of subcutaneous LMWH, subcutaneous or intravenous unfractionated heparin (UFH), subcutaneous fondaparinux or DOACs (dabigatran, rivaroxaban, apixaban, and edoxaban).[300-303] When using LMWH, weight-based therapeutic doses can be given once or twice daily and will depend on the agent selected. Intravenous UFH is initiated as a bolus (80 units/kg or 5,000 units), followed by continuous infusion (18 units/kg/hr) and adjusted to achieve an activated partial thromboplastin time (aPTT) corresponding to an anti-factor Xa activity of 0.3–0.7 unit/mL. If monitored subcutaneous UFH is chosen, then an initial dose of 17,500 units or 250 units/kg twice daily should be selected with the same aPTT target as for intravenous UFH. Fondaparinux is dosed at 5 mg daily for a patient weighing <50 kg, 7.5 mg daily for patients weighing 50–100 kg, or 10 mg daily for patients weighing >100 kg. It is recommended that LMWH or UFH or fondaparinux be overlapped with warfarin for at least 5 days, then discontinued when the international normalized ratio (INR) is 2 for 24 hours. In patients with either DVT or PE, warfarin should be dosed to maintain an INR of 2–3.[268] The DOAC class has been studied and approved for use in the treatment of acute VTE and prevention of VTE recurrence. When one of the DOACs is used for acute VTE treatment, the need for pretreatment with UFH or LMWH will depend on the agent selected. Patients prescribed apixaban or rivaroxaban can start therapy immediately upon VTE diagnosis, without need for parenteral pretreatment.[300,303] However, dabigatran and edoxaban both require pretreatment with UFH or LMWH for 5–10 days.[301,302] Dosing for the DOAC agents is dependent on renal function. Despite U.S. labeling, the DOACs ideally should be avoided in populations that were excluded from clinical trials (patients with creatinine clearance below 30 mL/min and, in the case of apixaban, those with a creatinine clearance <25 mL/min).[300-303] **Table 47-8** lists dosing recommendations for VTE treatment and reduction of VTE recurrence with DOACs.[298-301]

Patients experiencing a first episode of VTE due to a transient risk factor (such as drug-induced VTE) should undergo anticoagulation for 3 months.[268] If the provoking risk factor remains present (such as a case in which a culprit drug cannot be discontinued), the patient should remain on anticoagulation therapy until the risk factor is no longer present. Patients with a first episode of unprovoked VTE, inherited hypercoagulability, or antiphospholipid syndrome should receive anticoagulation for at least 3 months. After 3 months, therapy should be re-evaluated and risk-benefit considerations should be weighed to decide whether or not to employ extended duration therapy. Extended therapy is recommended for patients with a second occurrence of unprovoked VTE and the continuing use of treatment should be reassessed periodically (e.g., annually). Patients with cancer and a VTE should receive LMWH for the first 3 months, followed by therapy with either LMWH or warfarin until the cancer is resolved.[268] In rare circumstances, thrombectomy or thrombolysis may be considered. Inferior vena cava interruption using a filter is also an option for those with contraindications to anticoagulation therapy. The ACCP does not recommend routine use of either thrombolysis, thrombectomy, or vena cava interruption.[268]

Heparin should be discontinued in patients who experience thrombotic complications related to that drug and an alternative, nonheparin anticoagulant should be substituted. A direct thrombin inhibitor should be used initially for the treatment of patients with HIT or HIT and thrombosis (HITT).[241] Further studies evaluating the role of fondaparinux and the DOACs in the treatment of HIT are needed.[241]

When acute thrombotic complications secondary to warfarin occur, the drug should be immediately discontinued and UFH, LMWH, or fondaparinux should be initiated. Warfarin should be reinitiated only with extreme caution after the resolution of the thrombosis, with very slow dose titration and careful patient monitoring. Overlap of warfarin with therapeutic doses of the parenteral agent is necessary over 1 or more weeks until INR is >2.[242]

When a patient experiences drug-induced VTE, the culprit agent should be discontinued, when possible, and, in most instances, therapy with that drug should not be reinstituted. In cases in which the causative drug cannot be discontinued (e.g., in a patient with cancer who is responding appropriately to chemotherapy), anticoagulation should be initiated and continued for as long as therapy with the culprit drug is required. Hormonal therapy is not associated with an increased risk of recurrent VTE in women receiving therapeutic anticoagulation.[304] In such cases, the risks and benefits of drug continuation and anticoagulation must be carefully weighed and decisions made on a case-by-case basis.

Table 47-8 DOAC U.S. Labelled Dosing Recommendations for VTE Treatment and Reduction of VTE Recurrence

Drug	Dosage Recommendations	Recommended Pretreatment with UFH or LMWH
Dabigatran[301]	150 mg BID Renal dose adjustment CrCl ≤30 mL/min or on dialysis: Avoid use CrCl <50 mL/min with concomitant use of strong P-gp inhibitors: Avoid use	5–10 days parenteral pretreatment required
Rivaroxaban[300]	15 mg BID × 21 days; then 20 mg daily. May reduce to 10 mg daily for extended treatment after 6 months of therapy Renal dose adjustment CrCl <30 mL/min or on dialysis: Avoid use Concomitant use of strong dual inhibitors of P-gp and CYP3A4: Avoid use	No parenteral pretreatment required
Apixaban[303]	10 mg BID × 7 days; then 5 mg BID May reduce to 2.5 mg BID for extended treatment after 6 months of therapy Renal dose adjustment No recommendations for dose adjustment in renal impairment Concomitant use of strong dual inhibitors of P-gp and CYP3A4: Reduce dose by 50% if taking 10 mg or 5 mg dose; avoid use if taking 2.5-mg dose	No parenteral pretreatment required
Edoxaban[302]	CrCl >50 mL/min: 60 mg daily CrCl 15–50 mL/min: 30 mg daily Weight ≤60 kg: 30 mg daily Concomitant use of strong P-gp inhibitor: 30 mg daily Renal dose adjustment CrCl <15 mL/min or on dialysis: Avoid use	5–10 days parenteral pretreatment required

BID = twice daily, DOAC = direct acting oral anticoagulant, VTE = venous thromboembolism, UFH = unfractionated heparin, LMWH = low-molecular-weight heparin.

INFORMATION FOR PATIENTS

Patients receiving drugs known to cause VTE should know the signs and symptoms of DVT and PE and should be instructed to contact their primary care provider if they experience unilateral pain, tenderness, or swelling, especially in lower limbs, or if they experience sudden shortness of breath or chest pain. In addition, patients should be counseled about decreasing preventable risk factors, including smoking and obesity. Women receiving any type of estrogen therapy should be advised to discontinue treatment before, during, and after significant periods of immobilization. Extensive education regarding anticoagulant use, drug interactions, and monitoring is essential for patients treated for VTE. Finally, patients should be advised to keep all their healthcare providers apprised regarding their use of prescription and nonprescription medications and changes in drug therapy.

CHAPTER 48

Neutropenia and Agranulocytosis

Teresa C. Thakrar and Christopher A. Fausel

Neutropenia has been generally defined as an absolute neutrophil count (ANC) of <500 cells/mm^3 or <1,000 cells/mm^3 with an expected decline to <500 cells/mm^3.[1] The Infectious Diseases Society of America also defines neutropenia as an ANC of <500 cells/mm^3 or an anticipated decrease of the ANC to <500 cells/mm^3 but adds that the decline must be anticipated within the next 48 hours.[2] Neutropenia is classified as either acquired or intrinsic. Drug-induced neutropenia is an acquired neutropenia that is potentially life-threatening.[3,4] It occurs most commonly as an expected untoward effect associated with antineoplastic drugs. When noncytotoxic drugs cause a precipitous decline in neutrophil count, the condition is called agranulocytosis, and this disorder is well documented.[5,6] Agranulocytosis has been defined as a drug-mediated reduction in the peripheral ANC to <500 cells/mm^3 due to immunologic or cytotoxic mechanisms.[7]

CAUSATIVE AGENTS

It is common clinical practice in hematology/oncology to administer chemotherapy drugs in combination to treat the disease. The risk of myelosuppression with cytotoxic chemotherapy generally increases with an increasing number of agents per regimen, increasing drug dose, frequency, and duration of exposure.[8] Conventional cytotoxic chemotherapy drugs include the alkylating agents, antimetabolites, anthracyclines, topoisomerase inhibitors, taxanes, and vinca alkaloids; all may cause neutropenia when used alone or in combination chemotherapy regimens. Most molecular-targeted antineoplastic drugs cause a much lower incidence of neutropenia than conventional cytotoxic agents. Select tyrosine kinase inhibitors such as imatinib, dasatinib, nilotinib, bosutinib, and ponatinib cause neutropenia in patients with Philadelphia chromosome-positive (Ph+) acute and chronic leukemia, especially in those with more advanced disease. An in-depth discussion of specific chemotherapy regimens used in clinical practice and their risk for causing neutropenia is beyond the scope of this chapter, and the reader is referred to specialized sources for that specific information.[9,10]

Commonly used classes of drugs reported to cause agranulocytosis include nonsteroidal anti-inflammatory drugs (NSAIDs), antibiotics, antiplatelet, antithyroid, antirheumatic, antiarrhythmic, and antipsychotic agents.[10,11] In an extensive review of the medical literature published between 1966 and 2006, investigators found 980 cases of reported agranulocytosis. The authors evaluated each of these cases for causality and defined 6% as definite, 44% as probable, 49% as possible, and 1% as unlikely, using World Health Organization causality assessment criteria. A total of 125 drugs were found to be either definitely or probably causative.[12] A more recent surveillance study conducted in Berlin between 2000 and 2010 identified clozapine, sulfasalazine, methimazole, and thiamazole as the drugs with the highest probability of causing agranulocytosis, which is consistent with previous case-control studies. This indicates a relatively unchanged spectrum of causative agents, despite introduction of newly approved drugs.[13] **Table 48-1** lists drugs that have been reported to cause agranulocytosis.[12-32]

EPIDEMIOLOGY

Neutropenia is considered to be a dose-limiting toxicity for cancer treatments, and accordingly, documentation of this effect is meticulous in phase I, II, and III oncology trials.[33] Treatment of malignancies such as acute leukemia or procedures such as hematopoietic stem cell transplantation use drug doses and schedules to intentionally destroy the normal and diseased bone marrow cells to eradicate the primary disease. This strategy is illustrated by remission-induction therapy for acute leukemia, in which a state of aplasia persisting for several weeks is induced, followed by bone marrow recovery.[34] High-dose chemotherapy requiring an outside stem cell replacement source (allogeneic) used in bone marrow transplant procedures typically results in a 2- to 4-week period with bone marrow aplasia preceding engraftment of the transplanted bone marrow.[35]

The overall incidence of agranulocytosis has been reported in three large epidemiologic studies. A study conducted in Europe and Israel documented an incidence of agranulocytosis of 3.4 cases per million population per year.[36] This estimate is derived from data collected from hospitals by the International Aplastic Anemia and Agranulocytosis Study (IAAAS) over a 7-year period. The incidence of agranulocytosis in the United States was studied using computerized Medicaid billing data from three states from 1980 through 1985.[37] The overall incidence was 7.2 cases (range, 2.4–15.4) per million population per year. The Dutch healthcare system conducted a population-based, case-cohort study to determine the risk of agranulocytosis as a reason for hospital admission.[24] Review of hospital discharge data with subsequent case reviews yielded a mean incidence of 2 per million per year over 4 years.

The most recent epidemiologic data set consists of 17 hematology units in Europe contributing to case–control surveillance for agranulocytosis and aplastic anemia. The incidence of community-acquired agranulocytosis was 3.4 cases per million population per year with a mortality rate of 0.24 per million population per year and a case fatality rate of 7%.[17]

The risk of agranulocytosis associated with specific drug classes has been studied. A population-based, case-control study was performed with Medicaid claim data from six states to determine the association between NSAID use and agranulocytosis.[27] The odds ratio was found to be 3.3. No specific NSAID was associated with a higher risk, leading the authors to conclude that the low incidence does not necessitate establishing usage restrictions for any specific agent(s). These findings were similar to those of a previous IAAAS study.[15]

The epidemiology of agranulocytosis induced by cardiovascular drugs has also been evaluated, and an increased risk of agranulocytosis in patients treated for at least 1 week with propranolol, digoxin, dipyridamole, and procainamide was found.[23] IAAAS and others have documented an increased risk of agranulocytosis associated with trimethoprim–sulfamethoxazole and with the macrolide, β-lactam, and cephalosporin antibiotics.[18,19] Studies have been conducted to document the association of agranulocytosis with other drugs, including antithyroid agents, sulfonamides, sulfasalazine, and carbonic anhydrase inhibitors.[16,20,28,29,31]

The atypical antipsychotic drug clozapine is known to cause agranulocytosis. The manufacturer has instituted a stringent registration program for patients in which weekly white cell count monitoring is required before a drug supply is dispensed. Two large pharmacovigilance studies have examined the incidence of clozapine-induced agranulocytosis based on the registry data. In over 11,000 patients in the United States, the cumulative incidence of agranulocytosis at 1 year was 0.8%. These findings were corroborated by a European study that reported a cumulative incidence of clozapine-induced agranulocytosis of 0.73% in 12,760 patients.[21,22]

Table 48-1 Agents Implicated in Drug-Induced Neutropenia and Agranulocytosis

Drug	Incidence	Level of Evidence[a]
Abacavir[13]	NK	C
Acetaminophen[14]	NK	C
Acetazolamide[15]	NK	C

Quinacrine[17]	NK	C
Quinidine[22]	NK	C
Quinine[13]	NK	C
Ranitidine[11]	NK	C
Rituximab[11,a]	NK	C
Spironolactone[22]	NK	C
Streptomycin[17]	NK	C
Sulfasalazine[27,28,b]	0.6%	B
Tamoxifen[13]	NK	C
Ticlopidine[29,b]	2.4%	B
Tocainide[22]	NK	C
Trimethoprim–sulfamethoxazole[30]	NK	C
Valganciclovir[31]	NK	C
Valproic acid[13]	NK	C
Vancomycin[11]	NK	C
Zidovudine[11]	NK	C

NK = not known, NSAID = nonsteroidal anti-inflammatory drug.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] Ten or more published cases where agranulocytosis was deemed to be probably or definitely related to the drug.

MECHANISMS

Neutropenia secondary to chemotherapy occurs as a direct result of the cytotoxic effects of these agents on the bone marrow progenitor cells. The principal action of most antineoplastic agents is the disruption of cell proliferation, especially relating to cell division and deoxyribonucleic acid (DNA) synthesis.[38] These drugs all have the propensity to damage DNA during replication, particularly in rapidly growing tissues such as the bone marrow. Alkylating agents, antimetabolites, antimitotic drugs, anthracyclines, and topoisomerase inhibitors appear to cause neutropenia via this mechanism.[39] Newer immune-based therapies and molecular targeted drugs may also cause neutropenia; however, the mechanism involved is less clearly understood.[40]

Mechanisms of agranulocytosis may be divided into three broad categories: type I, immune-mediated; type II, direct toxicity; or type III, a combination of types I and II. Mechanisms of agranulocytosis, where known, are summarized in **Table 48-2**.[30,41-52] In type I agranulocytosis, assays such as leukoagglutination or enzyme-linked immunosorbent assay testing may be used to confirm the presence of antibodies directed against granulocytes.[53] Chlorpropamide has been shown to induce production of specific antibodies that inhibit granulocytic precursor cells in a dose-dependent manner.[54] Methimazole and propylthiouracil are associated with the formation of antibodies to neutrophils.[41,43,55] Procainamide-associated agranulocytosis is believed to result from an immune mechanism distinct from the one responsible for the systemic lupus erythematosus–like syndrome associated with this drug.[44]

Table 48-2 Mechanisms of Drug-Induced Neutropenia and Agranulocytosis

Drug	Mechanism
Antithyroid agents, β-lactam antibiotics, procainamide[40-43]	Immune-mediated, with antibody formation against granulocytes and granulocyte precursors
Cimetidine, cytotoxic chemotherapy, quinine, quinidine sulfonamides, ticlopidine[29,44-47]	Direct damage to myeloid precursors
Clozapine[49,50]	Metabolite-mediated depletion of adenosine triphosphate and glutathione-inducing apoptosis secondary to oxidative stress
Flecainide[48]	Hapten formation

Type II agranulocytosis is due to direct damage to myeloid precursor cells, leading to cell death. Cimetidine and quinidine have been reported to induce dose-dependent suppression of the bone marrow cells in vitro.[45,46] The suspected mechanism of ticlopidine-induced agranulocytosis involves a reactive metabolite interfering with normal neutrophil formation.[30,47] Activation of reactive metabolites via neutrophil myeloperoxidase mediates *N*-chlorination of sulfonamides, yielding direct neutrophil toxicity.[48]

Type III agranulocytosis may involve hapten formation, which has been linked to drugs such as flecainide and the penicillins.[49,50] There are cases in which multiple mechanisms appear to be involved with individual drugs. For example, clozapine-induced agranulocytosis may not be due solely to an immune-mediated process.[51] Accumulation of a nitrenium-containing metabolite of clozapine results in depletion of glutathione and adenosine triphosphate that results in apoptosis of neutrophils.[52] More evidence supporting this theory is that there is typically a delay of 14 weeks between clozapine rechallenge and neutrophil disappearance. This delay is inconsistent with a normal immune response.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The evaluation of patients with suspected drug-induced neutropenia and agranulocytosis requires a careful history and physical examination. In addition, a complete blood count with differential should be obtained; however, extensive laboratory evaluation or diagnostic procedures are generally not warranted on initial presentation, particularly if the ANC is >1,000 cells/mm^3. Signs and symptoms in patients with neutropenia and agranulocytosis are generally related to infectious complications (**Table 48-3**).[56] Without antibiotics or other treatment, patients commonly present with septicemia, but may also present with subtle symptoms of pneumonia, cellulitis, or oropharyngeal, periodontal, or perianal infection.[11] Patients with an ANC <500 cells/mm^3 are at risk for bacteremia from either the bowel or skin flora. Signs and symptoms of infection are typically blunted as a consequence of the inability to mount an adequate inflammatory response, especially when antibiotics are pre-emptively administered. In the absence of overt abnormal findings on physical examination, the clinician must rely on the presence of fever as the only reliable indicator of an active infectious process.[57]

Table 48-3 Signs and Symptoms Associated with Drug-Induced Neutropenia and Agranulocytosis

- Bronchitis
- Chills
- Fever
- Gingivitis/thrush
- Lethargy
- Myalgias

- Pharyngitis
- Sepsis
- Sinusitis
- Stomatitis
- Weakness

The timing of a neutropenic episode in relation to chemotherapy depends on the chemotherapy regimen administered; however, the ANC nadir during most myelosuppressive chemotherapy regimens occurs within 7–10 days of initiation of the most recent treatment cycle. Myeloablative and high-dose chemotherapy regimens may result in ANC nadirs within several days following the start of chemotherapy.[9,10]

Table 48-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Neutropenia and Agranulocytosis

- Aplastic anemia
- Autoimmune neutropenia
- Chronic idiopathic neutropenia
- Collagen vascular disorder
- Cyclic neutropenia
- Human immunodeficiency virus
- Hypersplenism
- Leukemia
- Myelodysplastic syndrome
- Pure white cell aplasia
- Radiation therapy
- Recent serious infection such as viral syndrome or sepsis
- Sjögren syndrome
- Toxic environmental exposure

Patients presenting with neutropenia who have not received cytotoxic chemotherapy require a thorough review of systems for evidence of a recent viral infection and a careful medication history that includes a review of the use of prescription and nonprescription medications and herbal supplements. The typical time course for the onset of agranulocytosis is 7–14 days following exposure to the causative drug. Once the causative agent has been discontinued, bone marrow recovery can typically be expected within 10–14 days if the neutropenia is secondary to a drug/antibody effect directed at mature cells or if neutrophil maturation has merely been halted. However, insult to myeloid precursors will likely cause delayed recovery of more than 14 days.[11] A more extensive diagnostic workup to rule out malignancy—particularly leukemia or lymphoma, human immunodeficiency virus, or idiopathic neutropenia—may be undertaken in cases in which cause is not established (**Table 48-4**). Anemia and thrombocytopenia were associated with neutropenia in 30% and 10%, respectively, of elderly patients who presented with more severe symptoms (i.e., sepsis and/or septic shock). Bone marrow aspiration and biopsy with immunologic and cytogenetic evaluation is indicated for these patients and those with neutropenia with an undefined cause to rule out other underlying pathology. Other clinically relevant causes of neutropenia to consider are sepsis, myelodysplastic syndromes, and hypersplenism.[11]

RISK FACTORS

Risk factors for chemotherapy-induced neutropenia include advanced age, previous exposure to chemotherapy or radiation therapy, poor nutrition, and end-organ dysfunction (**Table 48-5**). Factors known to increase the risk of infection in patients with neutropenia include the degree and duration of neutropenia, phagocytic function, compromise in cellular and humoral immunity, alteration in skin and mucosal physical defense barriers, and the patient's endogenous flora or nosocomial colonization.[58]

Table 48-5 Risk Factors for Drug-Induced Neutropenia and Agranulocytosis

- Advanced age
- Autoimmune disease
- Concurrent or previous treatment with radiation
- Female sex
- Genetic predisposition
- Infection preceding agranulocytosis
- Jewish ancestry (clozapine)
- Leukopenia during initiation of therapy (clozapine)
- Mononucleosis
- Multiagent chemotherapy regimens
- Polypharmacy
- Poor nutrition
- Prior treatment with chemotherapy
- Renal insufficiency or other end-organ dysfunction

More intensive chemotherapy treatment programs coupled with the greater prevalence of indwelling central venous catheters have increased the number of portals of entry for bacteria with the resultant disruption of skin and gastrointestinal barriers.[59] Chemotherapy or antecedent diseases such as myelodysplastic disorders impair the remaining vestiges of phagocytic defense in patients with neutropenia.[60] The increasing incidence of resistant gram-positive and gram-negative bacteria places patients with neutropenia at greater risk for morbidity and mortality from bacterial sepsis.[61]

Methods to stratify the risk of infection in febrile patients with neutropenia have been published.[62,63] A practical approach is to designate patients as either low-risk or high-risk for infection. Neutropenia with duration of <7–10 days has been defined as low-risk and typically occurs in patients treated for solid tumor malignancies. Neutropenia with duration >10 days is defined as high-risk and most commonly occurs in patients treated for acute leukemia or undergoing stem cell transplantation. As the duration of neutropenia increases, the risk of invasive fungal infection increases. Patients who have had neutropenia for 14 days have been found to have an increased incidence of invasive aspergillosis or candidiasis.[64]

Advanced age, female sex, mononucleosis, renal insufficiency, autoimmune disease, certain drug combinations, and genetic predisposition have all been associated with an increased risk for agranulocytosis (Table 48-5).[36] IAAAS noted that more than half of reported cases of agranulocytosis occurred in patients older than 50 years of age. The incidence of agranulocytosis in women is twice that reported in men. A higher incidence of agranulocytosis in older patients and in women was confirmed with analysis of the clozapine registry data in the United States.[21] The use of particular drugs in patients with specific disease states, such as the use of captopril in patients with renal failure, may increase the risk of agranulocytosis. In addition, case reports suggest that the concomitant use of captopril and probenecid or interferon may also increase the risk of agranulocytosis.[65] Genetic predisposition to agranulocytosis induced by drugs such as methimazole or clozapine may be present in patients with similar histocompatibility antigens within certain racial populations or with underlying immune disorders.[66,67] A recent study confirmed the role of the previously implicated *HLA-DQB1* variant in clozapine-associated neutropenia and further established the relationship between clozapine-associated neutropenia and genetic variants in members of a family of hepatic transporters, SLCO1B3 and SLCO1B7.[68] Dosing and duration of treatment may also play a role in frequency of drug-induced agranulocytosis. A retrospective study found that methimazole 30 mg daily was associated with a significantly higher incidence of agranulocytosis compared to those who received 15 mg daily (0.814% versus 0.219%, respectively).[69] Duration-dependent neutropenia was studied in β-lactam antibiotic usage in an analysis of published reports, where the incidence of neutropenia was found to differ significantly based on the duration of β-lactam antibiotic use. The incidence of neutropenia in patients treated with β-lactam antibiotics for 10 days or greater ranged from 5% to over 15%; whereas, the incidence of neutropenia in patients treated with <10 days of antibiotics was as low as 0.1%.[70]

MORBIDITY AND MORTALITY

Approximately half of patients with neutropenia who become febrile have an established apparent or occult infection. The risk is even greater when the ANC falls below 100 cells/mm^3, where 20% of febrile patients will have a potentially life-threatening bacteremia.[71] The morbidity and mortality associated with neutropenic fever has decreased as a result of prompt recognition, improved antibacterial prophylaxis and therapy, and the availability of colony stimulating factor support. Organisms such as *Pseudomonas aeruginosa, Staphylococcus aureus*, and *Streptococcus viridans* pose a mortal threat to patients with neutropenia.[72-74] In addition, invasive fungal infections, particularly *Candida* and *Aspergillus* species, are associated with a mortality risk of 90% or more in highly vulnerable populations, such as recipients of allogeneic stem cell transplants.[75]

In a study published in 1991, prognostic factors were evaluated in 168 episodes of agranulocytosis in which the overall mortality rate was 16%.[76] In a univariate analysis, the presence of renal failure, bacteremia, shock, advanced age, low lymphocyte count, low percentage of myeloid precursors, and high percentage of bone marrow plasma cells were significant indicators of poor survival. Bacteremia, renal insufficiency, and shock remained significantly correlated with a fatal outcome with multivariate analysis. More recently, the mortality rate has dropped to between 2.5% and 10% with advancements in therapeutic management of acute agranulocytosis and its complications.[77]

Mortality rates due to clozapine-induced agranulocytosis have been reported to be 0.016% to 0.017% in two studies that included over 24,000 patients.[21,22] A French database of 102 cases of agranulocytosis collected over a 15-year period revealed that 1 of 21 patients with antibiotic-induced agranulocytosis died.[19] The Swedish Drug Monitoring System reported mortality in 5 of 19 patients with sulfasalazine-induced agranulocytosis over a 6-year period.[29] A literature review cited 10% mortality in patients with agranulocytosis who had an ANC <100 cells/mm^3, and 3% in patients with an ANC >100 cells/mm^3.[12] Mortality increased from 14% in patients with agranulocytosis and no symptoms of infection to 29% in patients with symptoms of infection, regardless of neutrophil count.

PREVENTION

Prevention of neutropenia associated with cytotoxic chemotherapy can be optimized with two basic strategies. First, the dose of chemotherapy may be reduced in patients who have had a documented episode of neutropenia caused by a previous cycle of chemotherapy. This option is often pursued in patients receiving palliative chemotherapy. The second approach is to stimulate myeloid cell production with either filgrastim (granulocyte colony-stimulating factor [G-CSF]), pegfilgrastim (pegylated granulocyte colony-stimulating factor), or sargramostim (granulocyte macrophage colony-stimulating factor [GM-CSF]). The 2015 American Society of Clinical Oncology practice guideline makes practical recommendations for use of white blood cell growth factors in patients receiving chemotherapy.[78] This group recommended use of colony-stimulating factors if the chemotherapy regimen is associated with a documented incidence of febrile neutropenia of ≥20%; in patients who experienced neutropenic fever with a previous cycle of chemotherapy (secondary prophylaxis); after remission induction therapy for acute leukemia; and after high-dose chemotherapy to accelerate engraftment after stem cell transplantation.

Given the relatively low incidence of agranulocytosis, a practical method for early detection or prevention of this drug-induced disease has not been identified. There is no reliable, inexpensive assay or test available to identify the rare patient who may be at risk for agranulocytosis. Monitoring programs like the one implemented for patients receiving clozapine may lead to early detection of a declining white cell count. However, the high cost of implementing and administering such a comprehensive monitoring program makes it an impractical approach, except in very special circumstances. **Table 48-6** lists approaches to help prevent drug-induced neutropenia and agranulocytosis.

Table 48-6 Approaches to Help Prevent Drug-Induced Neutropenia and Agranulocytosis

Neutropenia due to cytotoxic chemotherapy

- Dose modification
- Prophylactic administration of filgrastim (or equivalent) or sargramostim

Agranulocytosis (general)

- Avoid drugs in the same class as an agent that previously caused agranulocytosis

Agranulocytosis due to clozapine

- Weekly monitoring of white cell count as recommended by manufacturer

MANAGEMENT

Neutropenia can lead to potentially life-threatening complications. As with other drug-induced diseases, discontinuation of the culprit agent(s) must always be a first consideration when patients present with drug-induced neutropenia or agranulocytosis. Drug-induced febrile neutropenia is considered a medical emergency and requires immediate evaluation and treatment. Because currently available diagnostic tests are not sufficiently rapid, sensitive, or specific for identifying or excluding specific microbial causes of a febrile episode, prompt administration of broad-spectrum antibacterial therapy is warranted after blood cultures have been obtained. Initial antibacterial therapy is directed at common organisms found in the gastrointestinal tract and on the skin. Broad-spectrum antibacterial therapy with reliable activity against *P. aeruginosa* is standard; the selection of specific antibiotics should be tailored based on local susceptibility patterns. Initial therapy with vancomycin may be instituted in clinical scenarios such as sepsis, mucositis, colonization with methicillin-resistant *S. aureus* or penicillin-resistant pneumococci, recent treatment with a fluoroquinolone antibiotic, or obvious catheter-related infections. Invasive fungal infection should be suspected in patients with neutropenia who have a fever that persists despite treatment with broad-spectrum antibiotics for 3–7 days. Institution of empirical antifungal therapy is standard practice in these cases. Patients with neutropenia in whom fever or other signs of infection develop should be treated quickly, following established treatment protocols. The Infectious Diseases Society of America has published guidelines for the management of neutropenic fever.[2]

The principal determinant of successful reversal of agranulocytosis is rapid recognition and immediate discontinuation of the causative agent. In some cases, the antineutrophil antibody test and a bone marrow biopsy and aspiration can help confirm a diagnosis of agranulocytosis. After the causative drug is discontinued, recovery of neutrophils generally occurs within two weeks. Specific guidelines for monitoring white cell counts in patients receiving clozapine have been developed to facilitate early detection of agranulocytosis. Given the rare occurrence of agranulocytosis with most drugs, however, the benefit of routinely monitoring blood counts in the general population is low relative to associated cost.

There is a large body of literature regarding the use of myeloid colony-stimulating factors to facilitate neutrophil recovery in agranulocytosis, although most are case reports or series or meta-analyses.[79-83] These agents support the survival and stimulate the proliferation of bone marrow progenitor cells, thereby increasing neutrophil counts.[84] G-CSF and GM-CSF are administered subcutaneously in doses of 5 mcg/kg/day and 250 mcg/kg/day, respectively. The pegylated formulation of G-CSF (pegfilgrastim) is administered subcutaneously at a fixed one-time dose of 6 mg. These agents are costly, but relatively well tolerated; the adverse effects are generally limited to bone pain, fever, and injection-site reactions. Given the rarity of agranulocytosis, it is unlikely that an adequately powered, randomized trial designed to evaluate the benefit of these agents in patients with agranulocytosis will be carried out. There are, however, several published reports describing the utility of colony-stimulating factors in patients with this drug-induced disease.[25,26,32,85] A cohort of 145 consecutive cases of agranulocytosis has been reported.[86] G-CSF 300 mcg/day was administered to 101 of these patients. Although no significant difference in mortality was noted in treated patients, G-CSF was found to decrease the median period of recovery to an

ANC of 1,000 cells/mm^3 from 7 to 5 days. In a review of published case reports of patients with agranulocytosis, Andersohn and colleagues found that those treated with G-CSF or GM-CSF had a shorter median duration of neutropenia (8 days versus 9 days) and among asymptomatic patients at diagnosis, had a lower proportion of infectious or fatal complications than untreated patients (14% versus 29%).[12] In addition to a reduction in duration of neutropenia, Andres and colleagues also reported benefits of G-CSF through decreased length of hospital stay and antibiotic duration, particularly in patients who presented with poor prognostic factors.[77,87]

INFORMATION FOR PATIENTS

Patients undergoing cytotoxic chemotherapy should be counseled regarding the risk of neutropenia, the symptoms associated with this drug-induced disease, and the importance of seeking prompt medical attention when these symptoms occur. Clear written and verbal instructions should be provided outlining information such as when to measure temperatures, what constitutes a fever, when to have a complete blood count checked, and who to call or where to seek treatment if a fever occurs. Patients should be informed that symptoms such as cough, mouth sores, sore throat, and shortness of breath necessitate immediate medical attention. Given the complexity of modern chemotherapy regimens and the risk for drug interactions with chemotherapy agents, antiemetics, and other supportive medications, the patient should ensure that the primary oncology providers are aware of all drugs being used and screen all new prescription and nonprescription drugs and herbal supplements for safety.

Patients who have experienced agranulocytosis should be advised to avoid other drugs within the same structural class when possible. If patients are to receive a myeloid colony-stimulating factor to accelerate neutrophil recovery, they must be taught the proper technique for subcutaneous injection and counseled regarding the risk of injection site reactions, fever, and bone pain. Because these agents are expensive, patients may need special assistance to find ways to offset the cost.

CHAPTER 49

Anemias

LeAnn B. Norris and Charles L. Bennett

Hematologic complications including anemia are an unfortunate consequence of modern pharmacotherapy. Most drug-induced anemias are well documented, and 20–25% are allergic or idiosyncratic.[1] Idiosyncratic reactions can be difficult to recognize and assign causality and may not be directly related to the culprit drug's pharmacology. Aplastic anemia, hemolytic anemia, megaloblastic anemia, and chemotherapy-induced anemia are the most common drug-related anemias.[2] Drug-induced anemias can lead to fatal outcomes and reported mortality rates range from 4% to 70%.[3]

The World Health Organization defines *anemia* as a hemoglobin (Hgb) <13 g/dL (130 g/L; <8.07 mmol/L) in men or <12 g/dL (<120 g/L; <7.45 mmol/L) in women.[4] A decrease in oxygenation secondary to anemia can result in a variety of symptoms, including fatigue, shortness of breath, skin pallor, and dizziness. Significant cardiovascular sequelae including arrhythmias and heart failure may occur in severe cases and when anemia occurs rapidly. The most common causes of anemia include blood loss, decreased production of red blood cells (RBCs) due to nutritional deficiencies (iron, folate, vitamin B_{12}), or increased destruction of RBCs (hemolytic anemia). These common causes of anemia must be ruled out prior to attributing anemia to drugs alone. A comprehensive medication history (current prescription and nonprescription medications, illicit drugs, herbal/nutritional supplements, and any medication exposures or changes that have occurred in the last 6 months) should be completed as part of the investigation into the cause(s) of anemia. The initial work-up for suspected drug-induced anemias should include a count of RBCs, white blood cells (WBCs) (with differential), and platelets as well as measurement of Hgb concentration, hematocrit (HCT), and mean corpuscular volume (MCV).

Risk factors for drug-induced anemias are not well defined and have not been well studied. In a study of over 600 cases, Bottiger et al.[5] determined the risk of drug-induced anemias increases with advancing age and the incidence is higher in women than in men. Genetic factors are perhaps the best understood risk factors for drug-induced anemias. Patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency are at risk for hemolytic anemia when exposed to certain drugs or chemicals. G6PD is the rate-limiting enzyme in the pathway that is responsible for maintaining adequate concentrations of nicotinamide adenine dinucleotide phosphate (NADPH), which maintains glutathione in its reduced form by reducing free radical formation. Oxidative stress in patients with G6PD deficiency denatures hemoglobin and causes hemolysis.[2] Glutathione deficiency, peroxidase deficiency, and β-thalassemia are other genetic disorders known to increase a patient's risk for drug-induced anemias.

APLASTIC ANEMIA

Aplastic anemia is a deficiency in RBCs, WBCs, and platelets (pancytopenia). It results in a hypoplastic bone marrow caused by the decrease in hematopoietic stem cells.[6,7]

CAUSATIVE AGENTS

Drugs found to have at least a moderate association with causing drug-induced aplastic anemia are listed in **Table 49-1**. The most common drug classes include anticonvulsants (carbamazepine and phenytoin), antibiotics (sulfonamides and linezolid), anti-inflammatory agents (nonsteroidal anti-inflammatory drugs), and chemotherapy agents.

Table 49-1 Agents Associated with Drug-Induced Aplastic Anemia

Drug	Incidence	Level of Evidence[a]

Acetazolamide[8]	1 case per 18,000 patient-years	B
Captopril[9-11]	NK	C
Carbamazepine[12-14]	3–4 cases per 100,000 years	B
Chloramphenicol[15-18]	NK[b]	B
Felbamate[19,20]	127 cases per 1 million users	B
Furosemide[21]	NK	C
Gold salts[22-25]	NK[c]	B
Imatinib[26-28]	NK	C
Linezolid[29-32]	1 case per 2,900 users	B
Mesalamine[56-58]	NK	C
Methimazole[33-36]	NK	C
NONSTEROIDAL ANTI-INFLAMMATORY DRUGS		
Diclofenac[37-41]	NK	C
Etodolac[42]	NK	C
Ibuprofen[43]	NK	C
Indomethacin[44]	NK	C
Salicylates[23]	NK	C
Sulindac[45]	NK	C
Phenytoin[46-52]	NK	C
Sulfonamides[5,23,53]	NK	C
Sulfisoxazole[18]	NK	C
Sulfasalazine[54,55]	NK	C
Temozolomide[59]	NK	C
ANTIPLATELET DRUGS		
Clopidogrel[60]	NK	C
Ticlopidine[61-63]	NK	C

NK = not known.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] Incidence of death is reported to be 1 per 21,000–36,000 users.

[c] Incidence of death is reported to be 1.5 per 10,000 prescriptions.

EPIDEMIOLOGY

Accurate prospective data regarding the incidence of aplastic anemia in the United States are lacking. The estimated incidence is approximately 0.6–0.61 cases per million population, although this is mostly based on retrospective, historical data and death registries.[5] This rate could be lower now as some of the older causative agents are no longer available or are not used as frequently. Epidemiologic studies suggest the incidence in Europe is 2 cases per million population.[64,65] Aplastic anemia is thought to be more common in Asia, with an estimated 4–6 cases per million population. This difference may be due to increased exposure to environmental factors, including toxic chemicals (benzene, pesticides, or insecticides) or viruses.[66]

MECHANISMS

There are two main types of aplastic anemia: inherited and acquired. Drug-induced aplastic anemia is thought to be acquired, although like other autoimmune disorders, genetic factors may predispose some patients to acquire aplastic anemia.[67,68] Three mechanisms are thought to cause damage to the pluripotent hematopoietic stem cells in acquired aplastic anemia.[69] The first mechanism, dose-dependent drug toxicity, most often caused by chemotherapy or radiotherapy, induces transient marrow failure due to suppression of proliferating cell lines. Hematopoietic suppression may also occur with continued dose escalation. The second mechanism is an idiosyncratic reaction where toxic metabolites of the parent drug cause the anemia. The third mechanism is immune-related and occurs when drug metabolites form complexes with cellular proteins within bone marrow cells. The hapten–protein complex formed due to an exposure to an inciting antigen (drug) activates cells and cytokines of the immune system, leading to the death of stem cells.[69] **Table 49-2** further describes potential mechanisms of the drug-induced anemias.

Table 49-2 Mechanisms of Drug-Induced Anemia

Anemia Type	Mechanism(s)
APLASTIC ANEMIA	
Chemotherapy platinum-based therapies[70-75]	Immunologic response—drug metabolites form complexes with cellular proteins and ultimately stimulate T-cell autoimmune destruction of hematopoietic precursors
HEMOLYTIC ANEMIA	
Cefazolin[76,77]	Drug absorption-cell-bound—nonimmune drug adsorption modifies red blood cell membrane and nonimmunologic protein binding

Cefotaxime[78] Cefotetan[79-82] Cefoxitin[83] Ceftizoxime[84,85] Ceftriaxone[86-90] Cefuroxime[91] Cephalothin[77,92] Quinidine[75] Quinine[75] Melthydopa[93,94]	Neoantigen—antibody binds drug and red cells Autoimmune—induces a drug-independent immune response
MACROCYTIC ANEMIA	
Phenytoin[14,46-52,95,96] Zidovudine[97-99]	Inhibition of DNA synthesis and replication, which leads to abnormal erythrocytosis and the production of megaloblasts, which are larger than normal erythrocytes
CHEMOTHERAPY–INDUCED ANEMIA	
Chemotherapy[26-28,70-75] (antimicrotubular agents, alkylating agents, camptothecins, platinum-based therapies, tyrosine kinase inhibitors)	Myelosuppressive chemotherapy destroys precursors, red cells, which results in a hypoproliferative state and eventually anemia; direct cytotoxicity stops DNA synthesis and/or replication leading to apoptosis of hematopoietic stem cells

DNA = deoxyribonucleic acid.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The clinical presentation of aplastic anemia may include the typical symptoms of anemia such as weakness, fatigue, headache, lethargy, palpitations, and shortness of breath (**Table 49-3**). Neutropenia typically occurs first followed by thrombocytopenia. Anemia usually occurs last due to the longer life span of RBCs.[100] Abnormal bleeding including mucosal or gingival bleeding may be present in addition to petechial rashes secondary to thrombocytopenia. Patients may develop infections, fever, and pharyngeal ulcerations although data suggest that fever may not always be present.[101] The average onset of symptoms is 6.5 weeks; however, symptoms have been reported to appear as early as days and as long as months following exposure to the offending drug.[102] An extensive work-up should be conducted including complete blood count (CBC) and a bone marrow biopsy. Chemical and medical drug exposures should be discussed as part of the patient interview and are considered an essential part of the differential diagnosis, although causality is often difficult to determine. The patient's past medical history including any earlier blood counts should be reviewed and knowledge of a personal or family history of pulmonary or hepatic diseases or any other single-lineage cytopenias may be helpful in narrowing the differential diagnosis.[101] Additional conditions to consider in the differential diagnosis for drug-induced anemia are listed in **Table 49-4**. A diagnosis of aplastic anemia can be made by the presence of two of the following criteria: a WBC count of 3,500 cells/mm^3 or less, a platelet count of 55,000 cells/mm^3 or less, or a hemoglobin value of 10 g/dL or less with a reticulocyte count of 30,000 cells/mm^3 or less.[103] Aplastic anemia is classified as severe when at least two of three peripheral blood smears show a neutrophil count of <500 cells/mm^3, platelet count of <20,000 cells/mm^3, and anemia with a corrected reticulocyte index of <1%.[3,104]

Table 49-3 Signs and Symptoms of Drug-Induced Anemia

Aplastic anemia

- Fatigue
- Headache
- Lethargy
- Neutropenia
  - Fever
  - Chills
  - Infection
- Tachycardia
- Thrombocytopenia
  - Easy bruisability
  - Petechiae
  - Bleeding
- Weakness

Hemolytic anemia, macrocytic anemia, and chemotherapy-induced anemia

- Fatigue
- Headache
- Lethargy
- Tachycardia
- Weakness

Table 49-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Anemia

Microcytic anemia

- Anemia of chronic disease
- Inherited disorders of iron metabolism or hemoglobin synthesis
  - Thalassemias

- Iron-deficiency anemia
- Lead intoxication
- Sideroblastic anemias

Normocytic anemia

- Acute bleeding
- Anemia of chronic disease
- Anemia of chronic kidney disease
- Anemia of chronic liver disease
- Aplastic anemia
- Leukemias and lymphomas
- Hypothyroidism
- Hemolytic anemia
    - Autoimmune
- Myelodysplasia

Macrocytic anemia

- Megaloblastic
    - Vitamin B_{12} deficiency
    - Folate deficiency
    - Inherited disorders of DNA synthesis
- Nonmegaloblastic
    - Alcoholism
    - Chronic obstructive pulmonary disease
    - Inherited disorders
    - Refractory anemias
        - Aplastic anemia
        - Myelodysplasia

DNA = deoxyribonucleic acid.

RISK FACTORS

Aplastic anemia is rare and drug-induced aplastic anemia is very rare. As a result, risk factors are not well defined. Risk factors for all drug-induced anemias can be found in **Table 49-5**.[3]

MORBIDITY AND MORTALITY

Aplastic anemia is the most serious of the drug-induced blood dyscrasias. Morbidity and mortality in patients with aplastic anemia typically occur as a result of infection and bleeding.[105] The average mortality rate is 50% and rises to >70% in severe cases with supportive care alone.[3]

Table 49-5 Risk Factors for Drug-Induced Anemias

Aplastic anemia

- Exposure to pesticides and chemicals
    - Benzene
    - Pesticides
    - Insecticides
- Occupational radiation exposure
- Viral exposure (e.g., hepatitis A)

Hemolytic anemia

- Infections
- Malaria
- Plasmodium
- Presence of rare inherited disorders
    - G6PD
    - Hereditary spherocytosis
    - Sickle cell anemia
    - Thalassemias
- Exposure to traumatic and microangiographic conditions
    - Valve replacement
    - Graft rejection

Macrocytic anemia

- Abdominal or intestinal surgery
- Diet low in vitamin B_{12}
- Chronic alcoholism
- Crohn disease
- Intestinal malabsorption syndromes
- Pernicious anemia

Chemotherapy-induced anemia

- Patient-related factors
    - Extent and type of cancer
    - Prior myelosuppressive chemotherapy
    - Prior skeletal radiation
- Regimen-related factors
    - Combination chemotherapy
    - Dose and schedule
    - Duration
- Specific agent administered
    - Platinum-based therapy
        - Cisplatin
        - Carboplatin
        - Oxaliplatin
    - Camptothecins
        - Topotecan
        - Irinotecan
    - Antimicrotubular agents
        - Docetaxel
        - Paclitaxel
        - Vinorelbine
    - Alkylating agents
        - Doxorubicin

        - Gemcitabine
        - Mitomycin C
    - o Tyrosine kinase inhibitor
        - Imatinib

G6PD = glucose-6-phosphate dehydrogenase deficiency.

PREVENTION

Prevention is challenging because drug-induced anemia is rare and unpredictable. Avoidance of drugs associated with aplastic anemia is recommended whenever alternatives are available. Regular hematologic monitoring is suggested when offending agents can't be avoided. Patient education and counseling may also play a role in prevention. Approaches to help prevent drug-induced anemia are outlined in **Table 49-6**.

Table 49-6 Approaches to Prevent Drug-Induced Anemia

- Careful documentation and patient education to prevent rechallenge when drug-induced anemias have occurred
- Consider modifying the chemotherapy regimen to a less myelosuppressive dose schedule or agent in patients with risk factors for developing chemotherapy-induced anemia
- Genetic testing (e.g., G6PD)
- Hematologic monitoring for drugs with higher risk of anemia

G6PD = glucose-6-phosphate dehydrogenase deficiency.

MANAGEMENT

Due to the high mortality rate, diagnosis and treatment should be initiated quickly. Goals for therapy include improving blood counts, decreasing the need for blood transfusions, eliminating symptoms, and minimizing the risk for infections. The first step is removal of the suspected agent. Supportive care strategies may also be necessary, including transfusion support, antibiotic use, and iron chelation therapy if iron overload is suspected from frequent transfusions. Additional treatment modalities are based on the disease severity. For nonsevere disease, removal of the offending agent and supportive care may be sufficient to reverse cytopenias. In more severe cases, immunosuppression or hematopoietic stem cell transplant (HSCT) may be required. Allogenic HSCT from a human-leukocyte-antigen (HLA)-matched sibling donor is the treatment of choice in patients <40 years of age. The 5-year survival rate in adults and children under the age of 18 years is 77% and 90%, respectively.[106,107] Not all patients have an HLA-matched sibling, and therefore allogeneic HSCT from an unrelated donor should be considered after a trial of immunosuppressive therapy. For patients who are not HSCT candidates or are older than 40 years of age, immunosuppressive therapy is recommended.

Combination therapy with antithymocyte globulin (ATG) and cyclosporine has been shown to achieve 5-year survival rates of 75–85%.[108] Other agents have been evaluated, but none have shown to be superior to ATG and cyclosporine.[106]

INFORMATION FOR PATIENTS

Patients should be educated on the importance of recognizing signs and symptoms of drug-induced anemia whenever they are prescribed medications with known risk. Immediate reporting of symptoms to a medical professional is imperative and routine monitoring of CBC over the course of therapy is recommended. For patients receiving long-term immunosuppressive therapy, education about the potential for infection and other known complications is necessary. Patients should understand the need for monitoring drug levels to ensure safety and efficacy while taking immunosuppressives.

HEMOLYTIC ANEMIA

Hemolytic anemia, a normocytic anemia, is a result of premature RBC destruction, or hemolysis. Hemolysis may occur either from changes in the intravascular environment or defective RBCs, both of which may be induced by exposure to various drugs. Hemolytic anemia can be immune-related or metabolic. The direct Coombs test (also known as a direct antiglobulin test) may be used to detect the presence of antibodies on red cells and determine if the hemolytic anemia is immune-related. If the test is negative, the cells are normal, and other secondary causes need to be ruled out.

CAUSATIVE AGENTS

Drugs found to have an association with drug-induced hemolytic anemia are listed in **Table 49-7**. Cases of drug-induced hemolytic anemia have been reported with cephalosporin and fluoroquinolone antibiotics. Other implicated drugs include H_2 antagonists, antihypertensives, and anti-inflammatory agents.

EPIDEMIOLOGY

As with other drug-induced anemias, establishing a clear causal relationship between a drug and hemolytic anemia can be difficult. Although rare, drug-induced hemolytic anemia does occur more frequently than drug-induced aplastic anemia. The estimated incidence of drug-induced hemolytic anemia has been reported as approximately 1 in 1.2 million individuals.[143]

MECHANISMS

Four mechanisms have been described for drug-induced hemolytic anemia. In the hapten mechanism, the body makes an antibody against the drug.[144] When exposure to the drug occurs again, the drug–antidrug complex forms, attaches to the RBC, activates the complement and leads to cell destruction.[78,145] Penicillin and cephalosporins, when given in high doses, are associated with this type of immune reaction. The onset of effects can occur over a week, and it may take several weeks for counts to normalize once the offending drug has been removed. Other agents associated with this type of hemolytic anemia include minocycline and streptomycin.[146]

With the immune bystander mechanism or the innocent bystander phenomenon, the drug binds to an antibody (e.g., IgG) to form an immune complex that attaches to the RBC, activates the complement, and leads to intravascular hemolysis.[78] Once the complement is activated, the complex (neoantigen) detaches itself and may bind to other RBCs, WBCs, and platelets. Only a small amount of drug is needed to cause this reaction, but this mechanism is often severe and may lead to hemoglobinuria and renal failure. The RBCs act as "innocent bystanders" in this type of immunologic reaction.[78] Quinine and several sulfonamides have been associated with this mechanism.

Table 49-7 Agents Associated with Drug-Induced Hemolytic Anemia

Drug	Incidence	Level of Evidence[a]
Acetaminophen[109]	NK	C
Ascorbic acid[110]	NK	C
Captopril[111]	NK	C
Carbamazepine[12-14]	3–4 blood dyscrasias per 100,000 prescriptions	B
Dapsone[112]	NK	C
CEPHALOSPORINS		
Cefazolin[75-77]	NK	C
Cefotaxime[75,113]	NK	C
Cefotetan[75,78-82]	NK	C
Cefoxitin[75,83]	NK	C
Ceftizoxime[84,85]	NK	C
	NK	C

Ceftriaxone[78,86-90]		
Cefuroxime[75,91]	NK	C
Cephalothin[77,92]	NK	C
Ceftazidime[75]	NK	C
Erythromycin[114]		
FLUOROQUINOLONES		
Ciprofloxacin[115]	NK	C
Levofloxacin[116]	NK	C
H_2-ANTAGONISTS		
Cimetidine[15,16,117,118]	NK	C
Famotidine[118]	NK	C
Ranitidine[118,119]	NK	C
Nizatidine[118]	NK	C
Interferon alfa[65,120,121]	NK	C
Isoniazid[46,122-127]	NK	C
Metformin[128,129]	NK	C
Methyldopa[93,94,130]	NK	C
Methylene blue[131]	NK	C
Nitrofurantoin[132]	NK	C
NONSTEROIDAL ANTI-INFLAMMATORY DRUGS		
Diclofenac[38-41,104]	NK	C
Etodolac[42]	NK	C
Ibuprofen[43]	NK	C
Indomethacin[44,104]	NK	C
Salicylates[23,104]	NK	C
Sulindac[45]	NK	C
Tolmetin[75]	NK	C
Piperacillin–tazobactam[75]	NK	C
Phenazopyridine[133,134]	NK	C
Probenecid[75]	NK	C
Quinidine[18,75]	NK	C
Quinine[18,75,100]	NK	C

Rasburicase[135,136]	NK	C
Ribavirin[120,137]	NK	C
Rifampin[138,139]	NK	C
Sulfacetamide[140]	NK	C
Sulfamethoxazole[141,142]	NK	C

NK = not known.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

Production of RBC autoantibodies is the third mechanism and has mostly been associated with methyldopa-induced hemolytic anemia.[93] Autoantibodies can be identified even in the absence of the offending drug or its metabolites. The mechanism by which methyldopa produces autoantibodies is not completely known. Approximately 10–20% of patients receiving methyldopa will develop a positive Coombs test; however, <1% of these patients will experience hemolysis. Hemolysis may occur from 4 months up to 2 years after initiation of methyldopa therapy.[94,147] Cladribine and fludarabine have also been associated with autoantibody production.[148]

The final mechanism for hemolytic anemia is nonimmunologic protein adsorption. This occurs when a drug binds to the RBC membrane followed by the binding of other proteins. These other proteins are not necessarily antibodies, but the net effect is modification of the RBC membrane.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Symptoms of drug-induced hemolytic anemia can present within 7–10 days or as long as months or even years after drug exposure. The Coombs test detects the presence of antibodies on RBCs and may be used as a confirmatory test and/or to rule out drug-induced causes.[117] The onset of symptoms may be directly related to the mechanism involved. Fatigue, malaise, pallor, and shortness of breath are all symptoms associated with hemolytic anemia (Table 49-3). Additional diseases that should be considered in the differential for hemolytic anemia can be found in Table 49-4.

RISK FACTORS

G6PD deficiency is the most common hereditary risk factor for drug-induced hemolytic anemia. Other associated abnormalities include thalassemias, hereditary spherocytosis, and sickle cell anemia. Additional risk factors are listed in Table 49-5.

MORBIDITY AND MORTALITY

Symptoms from drug-induced hemolytic anemia, especially severe symptoms, can increase morbidity. Mortality is low if the true offending drug is discontinued immediately. A case series suggests that mortality from drug-induced hemolytic anemia is approximately 4%.[149]

PREVENTION

Due to the unpredictability of drug-induced hemolytic anemia, prevention of this disease can be difficult. G6PD deficiency screening is a good prevention strategy in patients where initiating therapies associated with hemolytic anemia is imperative. Agents known to be associated with drug-induced hemolytic anemia should be avoided when possible. If the use of these agents is necessary, routine monitoring of CBC and other hematologic laboratory values is recommended. Patients should be educated about the signs and symptoms of hemolytic anemia. Additional prevention strategies can be found in Table 49-6.

MANAGEMENT

Treatment required for drug-induced hemolytic anemia is largely dependent on the severity of disease. Regardless of severity, however, identification and removal of the offending drug is the first step. Supportive care strategies should be implemented, including blood transfusions where necessary. Hemodialysis may be necessary in severe cases. Glucocorticoids may be utilized to treat autoimmune hemolytic anemia after the offending agent has been removed.[150] Both chimeric anti-CD20 monoclonal antibody rituximab and IgG treatments have been studied for treatment of drug-induced hemolytic anemia, but more data are needed before routine use can be recommended.[151,152] Patients who experience drug-induced hemolytic anemia should never be rechallenged with the offending agent.

INFORMATION FOR PATIENTS

Patients should be educated regarding the importance of recognizing signs and symptoms of drug-induced hemolytic anemia if and when they are prescribed medications known to carry that risk. Immediate reporting of symptoms of anemia to a healthcare professional is imperative, and routine monitoring of the CBC is recommended while receiving offending agents. Patients with hereditary risks (e.g., G6PD deficiency) should be alerted to the prescription and nonprescription medications that should be avoided to prevent drug-induced hemolytic anemia.

MACROCYTIC ANEMIA

Macrocytic anemias are characterized by an increase in the average volume of the RBC (an increased MCV) and increase in the diameter and thickness of the erythrocyte. Megaloblasts are large, immature, and dysfunctional RBCs, and macrocytic anemia can be megaloblastic or nonmegaloblastic. Nonmegaloblastic macrocytic anemias are most commonly associated with alcoholism or liver disease. Megaloblastic anemias are produced by disorders of deoxyribonucleic acid (DNA) synthesis, most commonly a result of folic acid and vitamin B_{12} deficiencies. Both dietary vitamin B_{12} and folic acid are necessary for DNA synthesis; in their absence DNA synthesis is halted, but ribonucleic acid (RNA) synthesis continues, leading to protein production and ultimately resulting in formation of megaloblasts and macrocytosis. Drugs may cause macrocytic anemia by interfering with DNA synthesis and replication leading to abnormal erythrocytosis and the production of megaloblasts.

CAUSATIVE AGENTS

A list of drugs found to have an association with drug-induced macrocytic anemia can be found in **Table 49-8**. Sulfonamides, metformin, phenytoin, zidovudine, and methotrexate are the most common agents with documented case reports of macrocytic anemia.

EPIDEMIOLOGY

The incidence of drug-induced macrocytic anemia is not well documented. Antimetabolites that inhibit DNA synthesis, such as methotrexate and hydroxyurea, often cause clinically insignificant macrocytosis. Methotrexate-associated macrocytic anemia occurs in approximately 3–9% of patients.[165] Zidovudine-induced macrocytosis has been reported as high as 80% in patients with human immunodeficiency virus (HIV) and may or may not lead to clinically significant anemia.[163,164]

MECHANISMS

Folate and vitamin B_{12} are essential to DNA synthesis. When there is a deficiency in either folate or vitamin B_{12}, DNA synthesis is halted but RNA synthesis continues, leading to an increase in megaloblasts and macrocytosis.[166] Mechanisms for disruption of DNA synthesis often vary by drug. Dihydrofolate reductase inhibition by either trimethoprim or methotrexate may cause macrocytic anemia. Phenytoin has been shown to decrease the absorption of folate or facilitate its clearance.[95] Zidovudine interferes with the heme protein by inhibiting DNA polymerase.[167] Metformin inhibits the absorption of vitamin B_{12}. Additional mechanisms for drug-induced macrocytic anemia can be found in Table 49-2.

Table 49-8 Agents Associated with Macrocytic Anemia

Drug	Incidence	Level of Evidence[a]
Azathioprine[46,153-156]	NK	C
Leflunomide[157]	NK	C
Mesalamine[56-58]	NK	C
Metformin[158,159]	NK	C
Nitrofurantoin[160,161]	NK	C
Phenytoin[14,46-52,95,96]	NK	C
SULFONAMIDES	NK	C
Sulfisoxazole[53]	NK	C
Sulfasalazine[18,54,55]	NK	C
Trimethoprim–sulfamethoxazole[142,162]	NK	C
Zidovudine[97-99,163,164]	NK	C

NK = not known.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

In the presence of low hemoglobin, an increased MCV is indicative of macrocytic anemia. Patients may experience common signs and symptoms of anemia, including fatigue, shortness of breath, and skin pallor. Additional signs and symptoms of drug-induced macrocytic anemia are listed in Table 49-3. Prior to a diagnosis of drug-induced anemia, nutritional deficiencies (e.g., folate and vitamin B_{12}) and malabsorption syndromes must be ruled out. Clinicians should consider documenting patients' baseline folate and vitamin B_{12} levels prior to initiating therapy with agents having high risk for causing drug-induced anemia.

RISK FACTORS

Risk factors for drug-induced macrocytic anemia are listed in Table 49-5. Conditions that result in a diet low in vitamin B_{12} as well as the presence of malabsorption syndromes and chronic alcoholism may increase a patient's risk of drug-induced macrocytic anemia.

MORBIDITY AND MORTALITY

Macrocytic anemia is not associated with significant morbidity or mortality. In severe cases, neurologic complications may occur, but these are reversible if caught early and properly treated.

PREVENTION

Avoidance of drugs that may be associated with macrocytic anemia is recommended. Regular hematologic monitoring is suggested when agents are known to cause macrocytic anemia can't be avoided. Patient education can also be important to prevention. Approaches to help prevent drug-induced anemia are listed in Table 49-6.

MANAGEMENT

Discontinuation of the offending drug is usually recommended in the treatment of drug-induced macrocytic anemia. When drug-induced macrocytic anemia occurs secondary to chemotherapy, it is typically considered an expected side effect of therapy and patients are treated symptomatically while therapy is continued. Supplementation of folic acid or vitamin B_{12} may be considered if their use won't alter the effectiveness of the treatment. Patients receiving trimethoprim–sulfamethoxazole may be given folinic acid, 5–10 mg up to 4 times a day, to correct macrocytic anemia.[168,169] Folic acid may be considered in patients receiving chronic methotrexate therapy to decrease side effects associated with that drug. Daily supplementation of folic acid (1 mg) may be utilized to correct drug-induced anemia caused by phenytoin or phenobarbital, although it may decrease the effectiveness of the seizure medications.[96]

INFORMATION FOR PATIENTS

Patients should be taught about the importance of recognizing signs and symptoms of drug-induced macrocytic anemia when they are prescribed medications known to increase risk. Immediate reporting of symptoms to a healthcare professional is important, and routine monitoring of CBC is recommended while patients are receiving drugs known to cause this disorder. For patients who are receiving long-term folic acid therapy, education about the reason for and the importance of supplementation is necessary.

CHEMOTHERAPY-INDUCED ANEMIA

Anemia occurs in 30–90% of all cancer patients.[170] Causes of anemia in cancer patients are often multifactorial, and the etiology can be difficult to determine. Other causes of anemia should be ruled out prior to diagnosing and treating a patient for chemotherapy-induced anemia (CIA).[171]

CAUSATIVE AGENTS

Chemotherapy agents associated with a relatively high incidence of mild-moderate anemia are listed in **Table 49-9**. Multiple drug classes, including alkylating agents (cyclophosphamide, carboplatin, cisplatin), antimetabolites (fluorouracil, gemcitabine, capecitabine, pemetrexed), topoisomerase inhibitors (doxorubicin, irinotecan, etoposide), and taxanes (paclitaxel and docetaxel), are associated with CIA. Other agents have been associated with different types of anemia: imatinib with bone marrow aplasia and oxaliplatin with hemolytic anemia.[26-28,172,173]

Table 49-9 Agents Associated with Chemotherapy-Induced Anemia

Drug	Incidence	Level of Evidence[a]
Cancer chemotherapy[70-74,171,174] (single agents and combination platinum-based therapies, camptothecins, antimicrotubular agents, alkylating agents)	37–41% of all cancer patients and as high as 50–60% of all solid tumor patients; grade 3 or 4 anemia in as high as 40–55% in cisplatin-based therapies	B
Capecitabine[175]	NK	C

Erlotinib[176]	NK	C
Imatinib[26-28]	NK	C
Lapatinib[175]	NK	C
Nilotinib[177]	NK	C
Oxaliplatin[172,173]	NK	C
Sunitinib[178]	NK	C
Sorafenib[178]	NK	C
Vemurafenib[179]	NK	C

NK = not known.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

EPIDEMIOLOGY

Depending on the tumor type, between 32% and 49% of patients are anemic at the time of cancer diagnosis. Rates of CIA are difficult to determine because patients with cancer can have multiple anemia etiologies.[180,181] The myelosuppressive effects of chemotherapy are thought to be cumulative; therefore, the incidence of anemia may steadily increase with additional cycles of chemotherapy.[182]

MECHANISMS

Chemotherapy impairs hematopoiesis and disrupts RBC precursors' synthesis.[183] The exact mechanism of chemotherapy-induced anemia can be multifactorial, including a decrease in RBC production and a decreased erythropoietin production or decreased responsiveness to endogenous erythropoietin. Agents that cause nephrotoxicity, including cisplatin, also inhibit erythropoiesis by affecting erythropoietin production in the kidney. Anemia from underlying comorbidities, chronic blood loss, the cancer itself, or a combination of these factors may exacerbate the anemia.[184,185] Cancer cells can also suppress hematopoiesis through bone marrow infiltration and increased cytokine release that decreases the production and survival of RBCs.[181] Nutritional deficiencies, hemolysis, and coagulopathies may also contribute to anemia in cancer patients. Additional mechanisms are listed in Table 49-2.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Signs and symptoms of CIA are listed in Table 49-3 and are similar to those found in patients with other causes of anemia. According to guidelines for patients with cancer, a Hgb level of 11 g/dL or below should prompt an evaluation of anemia. In patients with a baseline Hgb >11 g/dL, a drop in Hgb of 2 g/dL or more in a relatively short period of time is a cause for concern and assessment.[181] Initial assessments should include a CBC with differential, iron studies, folate, vitamin B_{12}, and a detailed history and physical exam including onset of symptoms, comorbidities, and any exposure to chemotherapy agents or radiation. If a deficiency in iron, folate, or vitamin B_{12} is found, the deficiency should be treated accordingly. Any other cause of anemia that may be rectified independent of cancer therapy should also be treated as indicated. When no such etiology is identified, the myelosuppressive chemotherapy should be considered the cause of anemia.[181]

RISK FACTORS

Risk factors for CIA can be divided into two categories: patient-related risk factors and regimen-related risks (Table 49-5). Individual characteristics that increase the incidence of bone marrow suppression or predispose the patient to becoming symptomatic with anemia are considered patient-related risks. Radiation therapy, especially to the bones, can increase the risk of RBCs. Patients with a history of receiving chemotherapy may have ongoing anemia of chronic disease. Cancer that infiltrates the bone marrow may also increase the risk of CIA due to weakened erythropoiesis. Patients with significant cardiovascular, pulmonary, or cerebral vascular disease may also have an increased risk of CIA due to lower baseline levels of Hgb. Regimen-related risks include the regimen’s anemic potential, length of therapy, the use of combination versus single-agent therapy, dosage, and administration schedule.

MORBIDITY AND MORTALITY

CIA can significantly affect patients’ quality of life, due either to the symptoms of anemia or the treatment required to treat the anemia. Prior to initiating therapy, the risks of treatment must be weighed against the benefits. Prior to the use of blood transfusion, documented complications (e.g., transfusion-related reactions, transfusion-associated circulatory overload, bacterial contamination, viral infections, and iron overload) should be considered.[181] Although they may help reduce the need for RBC transfusions, erythrocyte stimulating agents (ESAs) are associated with significant risks including venous thromboembolism (VTE), tumor progression, and death.[181,186] For this reason, ESA therapy for chemotherapy-induced anemia is only recommended in patients who have a noncurable, nonmyeloid cancer who are actively receiving chemotherapy.

PREVENTION

A thorough assessment should be conducted at the onset of chemotherapy to determine if the patient may be at risk for CIA. Evaluation of underlying risk factors, the type of tumor the patient has, and the chemotherapy regimen being utilized is appropriate. If the patient's risk of CIA is high, the healthcare team may want to consider an alternative treatment regimen. When treating with curative intent, however, substituting treatment regimens simply to avoid CIA may not be appropriate.

MANAGEMENT

Prior to initiating treatment for CIA, a risk assessment based on the causative agent(s), the patient's past medical history, and baseline laboratory values will help determine the initial intervention plan. A decision to use blood transfusions should be based on the patient's symptoms (onset, severity, and duration) and comorbidities rather than on Hgb alone.[181] If a rapid correction in Hgb is needed, a blood transfusion is the only option. Administration of 1 unit of packed red blood cells (PRBC) is estimated to increase a patient's hemoglobin by 1 g/dL nonbleeding.

ESAs approved for use for CIA include epoetin alfa and darbepoetin alfa. Unlike blood transfusions, ESAs can take several weeks to trigger a hemoglobin response. The National Comprehensive Cancer Network (NCCN) guidelines recommend specific dosing strategies to ensure appropriate treatment and to minimize side effects.[181] Risks versus benefits should be discussed with the patient prior to initiation. Studies have demonstrated a decrease in survival and tumor progression in patients receiving ESA therapy. VTE and hypertension are significant effects that may also occur and should be monitored. As a result, the U.S. Food and Drug Administration (FDA) has added a boxed warning to ESA labeling highlighting the side effects. To minimize complications when ESA therapy is deemed necessary, the lowest dose required to avoid the need for blood transfusions should be used.[187,188] ESA should also be discontinued within 6 weeks if chemotherapy is no longer used. Patients who have a curable cancer should not be treated with ESA therapy. Recommended dosing of ESAs in provided in **Table 49-10**.

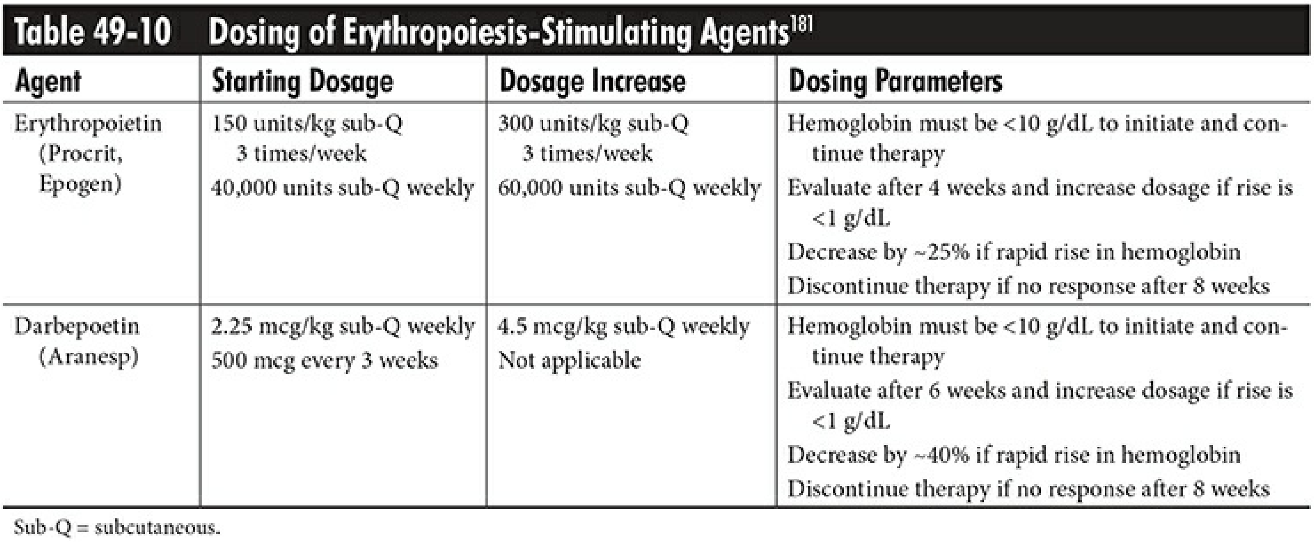

Table 49-10 Dosing of Erythropoiesis-Stimulating Agents[181]

Agent	Starting Dosage	Dosage Increase	Dosing Parameters
Erythropoietin (Procrit, Epogen)	150 units/kg sub-Q 3 times/week 40,000 units sub-Q weekly	300 units/kg sub-Q 3 times/week 60,000 units sub-Q weekly	Hemoglobin must be <10 g/dL to initiate and continue therapy Evaluate after 4 weeks and increase dosage if rise is <1 g/dL Decrease by ~25% if rapid rise in hemoglobin Discontinue therapy if no response after 8 weeks
Darbepoetin (Aranesp)	2.25 mcg/kg sub-Q weekly 500 mcg every 3 weeks	4.5 mcg/kg sub-Q weekly Not applicable	Hemoglobin must be <10 g/dL to initiate and continue therapy Evaluate after 6 weeks and increase dosage if rise is <1 g/dL Decrease by ~40% if rapid rise in hemoglobin Discontinue therapy if no response after 8 weeks

Sub-Q = subcutaneous.

INFORMATION FOR PATIENTS

Patients should be educated to recognize the signs and symptoms of anemia if they are to receive chemotherapy. Immediate reporting of symptoms to a healthcare professional is imperative and routine monitoring of CBC is recommended while the patient is exposed to possible causative agents. The potential risks and benefits of ESA therapy must be discussed with patients prior to the use of those agents, and the FDA requires informed consent under the Risk Evaluation and Mitigation Strategy (REMS) program. A medication guide must also be provided to patients prior to initiation of therapy to ensure understanding of the risks and benefits of using ESAs.

CHAPTER 50

Osteoporosis and Osteomalacia

Laura M. Borgelt and Danielle R. Fixen

The United States Bone and Joint Initiative, as part of the Global Alliance for Musculoskeletal Health, is the U.S. National Action Network of the Global Bone and Joint Decade.[1] It is a group of patient and healthcare professional organizations, medical schools, government agencies, health-system providers, and industry established to improve prevention of bone and joint disorders and the quality of life for those affected by these conditions. The primary goal of this initiative is to advance care and reduce the burden of disease for individuals with various musculoskeletal conditions. Other goals include increasing awareness and educating the world on the increasing societal impact of musculoskeletal injuries and disorders, empowering patients to participate in decisions about their care and treatment, increase global funding for prevention activities and treatment research, and continually seeking and promoting cost-effective prevention and treatment of musculoskeletal injuries and disorders. Although many musculoskeletal conditions are incorporated into its aims, osteoporosis is recognized as a significant contributor to the healthcare burden worldwide. The spirit of this initiative suggests that all healthcare providers should increase attention to screening patients, provide education, perform research, and work to help ensure proper management and follow-up of patients diagnosed with these and related disorders as a way to help prevent the devastating consequences of fracture and its potential complications of chronic pain, disability, and death.[1] This includes evaluation of medications that may cause musculoskeletal conditions such as osteoporosis and osteomalacia.

Deterioration of bone mass not associated with other chronic illness is referred to as primary osteoporosis and is related to aging and decreased gonadal function. Secondary osteoporosis can be viewed as low bone mineral density or increased risk of fragility fracture caused by any factor other than aging or postmenopausal status, such as medical disorders or medication exposures.[2] Differentiating between primary osteoporosis and the various causes of secondary osteoporosis can be challenging due to the many disease states and drugs that may be involved. Individuals with secondary osteoporosis experience bone loss greater than that caused by aging and menopause in primary osteoporosis, and it is especially important, therefore, to identify, accurately evaluate, and appropriately treat these patients.[2]

Osteomalacia is a softening of the bones, typically due to vitamin D deficiency and less commonly due to hypophosphatemia or hypocalcemia. In children, this condition is called rickets. Osteomalacia can cause fatigue, bone pain, muscle weakness, and difficulty walking and result in bone fracture.[3] Drugs that may affect vitamin D metabolism should be cautiously prescribed in patients at risk for the development of osteomalacia.

CAUSATIVE AGENTS

Medications commonly associated with osteoporosis or osteomalacia are listed in **Table 50-1**.[4-59] The impact of each of the medications on bone mineral density (BMD) or fracture incidence (or both) is presented where data are available.

Glucocorticoids are the most common cause of drug-induced osteoporosis, and their effects appear to be dose- and duration-dependent.[2,45] An increased risk of fracture has been reported for patients taking prednisone 2.5 mg or more daily; national recommendations indicate prednisone ≥5 mg/day (or equivalent exposure to other glucocorticoids) for ≥3 months may result in low bone mass or bone loss.[60] Approximately 30–50% of patients receiving long-term glucocorticoid therapy will experience a fracture.[47,48]

EPIDEMIOLOGY

It is estimated that over 200 million people worldwide suffer from osteoporosis.[61] Approximately 10 million Americans have osteoporosis and an additional 43 million have low bone mass or osteopenia as defined by the World Health Organization (WHO).[60,62] This accounts for approximately 55% of people age 50 years and older in the United States. More than 2 million fractures were attributed to osteoporosis in 2005 and this number is expected to exceed 3 million by 2025.[63] Fracture rates in other countries tend to vary. For example, wrist and hip fracture in the United Kingdom occurs at a rate about 30% lower than that in the United States and hip fracture incidence differs among various Asian countries.[64] Although secondary osteoporosis is known to be common, precise data regarding its incidence are not available. More than two thirds of men, more than half of premenopausal women, and approximately one third of postmenopausal women with osteoporosis have a disease state or drug therapy contributing to their bone loss.[65] The incidence of drug-induced bone loss or increased bone fragility is difficult to quantify, as medications usually contribute to an increased risk of osteoporosis rather than represent its sole cause. Table 50-1 provides information regarding the risks for bone loss and fractures with drug use.

Vitamin D deficiency is one of the most common secondary causes for bone loss and fractures, especially in the elderly. Prolonged, severe vitamin D deficiency can lead to poor bone mineralization and osteomalacia. The overall incidence of vitamin D–induced osteomalacia is not precisely known, but it appears to be lower in the United States than in many other countries because of fortification of milk with vitamin D.

MECHANISMS

The process through which bone undergoes repair and readjustment is called bone remodeling, and there are three main cells involved in this process: osteoblasts, osetocytes, and osteoclasts. Osteoblasts are derived from a mesenchymal stem cell precursor and are responsible for synthesizing the organic bone matrix (osteoid) and mineralizing the bone. Osteocytes, which are retired osteoblasts trapped in bone, are considered the communication cells and help coordinate the remodeling cycle at a particular site. Osteoclasts are derived from hematopoietic precursors of the monocyte–macrophage lineage and are responsible for bone resorption.

The remodeling process begins when the receptor activator of nuclear factor kappa-B ligand (RANKL), which is secreted from the osteoblast precursor cells, binds to its receptor activator of nuclear factor kappa-B (RANK) on the surface of the osteoclast precursor cells. This leads to the differentiation and activation of mature osteoclasts, which in turn resorb bone through the degradation of the protein matrix and demineralization. Once bone resorption is complete at that site, cytokines and growth factors that are involved in chemotaxis, proliferation, and differentiation of osteoblasts are released. Osteoprotegerin (OPG), a soluble decoy protein, is secreted by the osteoblast precursor cells and competes with RANKL for RANK. This leads to inhibition of the differentiation and activation of osteoclasts, thus stopping bone resorption at that site. Mature osteoblasts form new bone by first laying down collagen and other noncollagenous proteins to create the osteoid and then mineralize it. When bone formation is complete, mature osteoblasts become either lining cells or osteocytes or undergo apoptosis. That section of bone is now in the resting phase, called quiescence, until a new remodeling cycle is activated.

Table 50-1 Agents Implicated in Drug-Induced Osteoporosis and Osteomalacia

Drug	Incidence	Level of Evidence[a]
Antiepileptics[4-7,b]	BMD: 0.35–1.8% bone loss Fracture: RR 2.18; 95% CI 1.94–2.45	B
Antineoplastic agents[8,9]	BMD: 6.08–7.24% bone loss Fracture: OR 1.49; 95% CI 1.25–1.77	B
Antiretroviral therapy[10-13]	BMD: 1–6% bone loss; patients receiving antiretroviral therapy with osteoporosis—OR 2.38; 95% CI 1.20–4.75; patients receiving PI with osteoporosis—OR 1.57; 95% CI 1.05–2.34 Fracture: Not known	B
Aromatase inhibitors[14-19]	BMD: 2.5–5% bone loss in spine and 1.5–5% in hip (average 2% bone loss per year) Fracture: 7.1% with anastrozole; 5.7% with letrozole	B
Canagliflozin[20,21]	BMD: Decreases bone mineral density in total hip Fracture: 2.7%; difference versus noncanagliflozin 0.8%; 95% CI 1–1.74	B
Cyclosporine[22]	Not known—usually confounded by concomitant glucocorticoid use	C
Depot medroxyprogesterone[23-27,c]	BMD: 2–8% bone loss Fracture: Incidence rate ratio versus nonusers 1.41 (95% CI 1.35–1.47)	B
Furosemide[28,29]	BMD: Bone loss may increase by 0.3% per year of treatment Fracture: RR 3.9; 95% CI 1.5–10.4	B
Gonadotropin-releasing hormone agonists[30,31]	BMD: 6–7% hip bone loss; 5–10% trabecular bone loss Fracture: Vertebral RR 1.45; 95% CI 1.19–1.75; hip RR 1.3; 95% CI 1.1–1.53	B
Methotrexate (high dose)[32-35]	BMD: Bone loss 0.2–1.6% Fracture: 12–45%	C
	BMD: 10–12% bone loss	B

Levothyroxine (oversupplementation)[36-39]	Fracture: HR 1.56; 95% CI 1.03–2.37 (highest with doses >150 mcg/day)	
Proton pump inhibitors[40,41]	BMD: Not known Fracture: HR 1.28; 95% CI 1.13–1.44	B
Selective serotonin reuptake inhibitors[42,43]	BMD: 4.4–6.2% bone loss Fracture: RR 1.61; 95% CI 1.49–1.74	B
Systemic glucocorticoids[44-48]	BMD: Density consistently lower than that expected for group of similar age and sex Fracture: 30–50%; major fracture RR 1.25; 95% CI 1.07–1.45 and hip fracture RR 1.61; 95% CI 1.18–2.20	A
Thiazolidinediones[49-51]	BMD: Accelerated bone loss by 0.6–1.2%/yr Fracture: Up to 9% Women: OR 1.94; 95% CI 1.60–2.35; p <0.001 Men: OR 1.02; 95% CI 0.83–1.27; p = 0.83	B
Unfractionated heparin and low-molecular-weight heparin[52-55,d]	BMD: Up to 30% bone loss Fracture: 2.2–3.6%	B
Vitamin A (dose >1.5 mg/day of retinol form)[56-59]	BMD: 10–14% bone loss Fracture: Increased RR	B

BMD = bone mineral density, CI = confidence interval, OR = odds ratio, RR = relative risk, PI = protease inhibitor.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] Most evidence with phenytoin and phenobarbital (limited or conflicting data with carbamazepine and valproic acid).

[c] Evidence of at least partial recovery after discontinuation.

[d] Most data related to long-term heparin use (≥15,000 units for ≥6 months) rather than low-molecular-weight heparins.

Under normal circumstances, bone remodeling should not lead to a net loss of bone. However, after peak bone mass is achieved (typically between 18–25 years of age), physiologic changes occur that result in bone resorption exceeding bone formation (typically around 40 years of age).[60] During perimenopause and for up to 5–7 years after menopause, women can experience an accelerated rate of bone loss due to a drop in circulating estrogen, leading to an increase in osteoclastic activity and heightened bone resorption. In the elderly, bone loss at a rate of approximately 0.5–1% per year is caused by a combination of an accelerated rate of bone resorption and a reduced rate of bone formation. Decreased calcium absorption and sex hormone concentrations and impaired osteoblast function appear to be the largest contributors to bone loss in the elderly.

Drugs can contribute to bone loss in patients of any age by interfering with various steps in the bone remodeling process. The most common mechanism involves increased osteoclast maturation and function leading to accelerated bone resorption. Several drugs increase bone resorption by reducing sex hormone production. Suppressed osteoblast activity, increased bone resorption, and impaired bone mineralization can also be caused by medications.[20,66] Glucocorticoid use is the most common secondary cause of osteoporosis and the third most common cause of osteoporosis overall.[67] Glucocorticoids are extremely damaging to bone tissue because they can negatively affect all aspects of bone remodeling. They decrease bone formation through effects on osteoblasts.[67,68] These drugs can interfere with natural repair mechanisms through increased apoptosis of osteocytes.[67] They increase bone resorption by increasing the expression of RANKL and decreasing the expression of OPG, reducing sex hormone production, and causing a negative calcium balance through a decrease in calcium absorption and an increase in urinary calcium excretion.[67-69]

Endogenous production of cholecalciferol (vitamin D_3) from exposure to ultraviolet B (UVB) light is the primary source of vitamin D. Activation of cholecalciferol occurs in the liver and the kidney. Synthesis can be reduced by factors that interfere with the penetration of UVB light into the skin or impair the various steps in its conversion. The diet is a secondary source for vitamin D, although there are very few foods that have naturally high vitamin D content. Vitamin D is important for calcium homeostasis. Adequate concentrations of vitamin D are needed to ensure appropriate intestinal calcium absorption and adequate concentrations of calcium are needed for proper mineralization of bone. Inadequate body stores of vitamin D can lead to insufficient calcium absorption and decreased serum calcium concentrations, which can lead to secondary hyperparathyroidism. Parathyroid hormone decreases calcium excretion by the kidney and increases bone resorption to mobilize calcium stores, thus increasing serum calcium concentrations. Increased bone turnover with bone loss and poor bone mineralization are consequences of severe vitamin D deficiency. Vitamin D deficiency has also been associated with muscle weakness and an increased risk for falls.[70] Antiepileptic medications including phenytoin, carbamazepine, and phenobarbital have been implicated in contributing to severe vitamin D deficiency and osteomalacia. Interference with vitamin D metabolism and subsequent hypocalcemia is the most common mechanism for drug-induced osteomalacia. Less common mechanisms include hypophosphatemia and a direct effect on mineralization.[71] **Table 50-2** describes mechanisms of drug-induced osteoporosis and osteomalacia.

Table 50-2 Mechanisms of Drug-Induced Osteoporosis and

Osteomalacia

Drug	Mechanism
Antiepileptics: phenytoin, carbamazepine, phenobarbital[71-73]	May cause severe vitamin D deficiency and osteomalacia; may induce the cytochrome P-450 enzyme system leading to inactivation of vitamin D, which decreases calcium uptake
Valproic acid[66]	Osteomalacia possibly due to increased renal excretion of calcium and phosphorus
Antiretroviral therapy[74] Nucleoside reverse-transcriptase inhibitors: tenofovir, zidovudine, didanosine, lamivudine[75] Protease inhibitors: nelfinavir > indinavir > saquinavir > ritonavir[76] Nelfinavir, lopinavir,[76] indinavir	Increase osteoclastogenesis (in vivo) Increase osteoclast activity (ex vivo data) Decrease expression of OPG (ex vivo data) Attenuate the function and recruitment of osteoblasts (in vivo)
Antineoplastic agents: bicalutamide, busulfan, cyclophosphamide, ifosfamide[71]	Bone loss secondary to inhibitory effects on gonadal function May cause renal phosphate wasting leading to osteomalacia and bone loss
Aromatase inhibitors (letrozole, anastrozole)[14]	Inhibit peripheral conversion of androgens to estrogens, leading to lower estrogen levels
Canagliflozin[77]	Increases serum phosphate concentration causing increased PTH concentration leading to bone resorption
Cyclosporine[22]	Accelerates bone turnover
Depot medroxyprogesterone[26]	Suppresses the hypothalamic-pituitary-ovarian axis leading to reduced estrogen
Furosemide[28]	Inhibits the sodium–potassium–chloride cotransporter in the thick ascending limb of Henle leading to renal calcium excretion; bone loss appears to be minimized by increases in PTH and 1,25-dihydroxyvitamin D concentrations and a subsequent increase in intestinal calcium absorption
GnRH agonists (e.g., leuprolide, goserelin)[31]	Decrease production of sex hormones
Methotrexate (high dose)[78]	Increases apoptosis of osteocytes and number of osteoclasts
Levothyroxine (oversupplementation)[79,80]	Possibly increases bone resorption
Proton pump inhibitors	Cause calcium malabsorption secondary to acid suppression
Selective serotonin reuptake inhibitors[42,43]	May inhibit serotonin transporter system in osteoblasts leading to reduced activity and bone formation
	Decrease bone formation:

Systemic glucocorticoids[67-69]	• Decrease proliferation and differentiation of osteoblastic cells and enhance apoptosis of osteoblasts • Interfere with the bone's natural repair mechanism through increased apoptosis of osteocytes (bone's communication cells) Increase bone resorption: • Increase the expression of RANKL and decrease the expression of OPG, its soluble decoy receptor, both of which will increase osteoclastogenesis • Reduce estrogen and testosterone concentrations by decreasing the production of luteinizing hormone from the pituitary and through adrenal suppression • Cause a negative calcium balance by decreasing calcium absorption and increasing urinary calcium excretion
Thiazolidinediones (pioglitazone, rosiglitazone)[49,81,82]	Reduce osteoblastic bone formation by increasing adipogenesis and decreasing osteoblastogenesis
Unfractionated heparin/low-molecular-weight heparin[83]	Decreases bone formation and increases bone resorption by inhibiting the expression of OPG
Vitamin A (large amounts of retinol form)[84,85]	Increases osteoclastic activity and decreases osteoblastic activity leading to increased bone resorption; possible interference with vitamin D function

GnRH = gonadotropin-releasing hormone, PTH = parathyroid hormone, OPG = osteoprotegerin, RANKL = receptor activator of nuclear factor kappa-B ligand.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The clinical presentation of patients with drug-induced osteoporosis is not generally different from that of patients presenting with osteoporosis from other causes (**Tables 50-3** and **50-4**).

Table 50-3 Signs and Symptoms Associated with Drug-Induced Osteoporosis and Osteomalacia[60,87]

Osteoporosis

- Acute or chronic pain, or no pain (vertebral fracture)
- Acute pain (nonvertebral fracture)
- Decreased bone mineral density (T-score −2.5 and below or Z-score −2 and below[a])
- Kyphosis (Dowager's hump)
- Low trauma fractures

Osteomalacia

- Decreased bone mineral density
- Diffuse skeletal pain
- Hyperparathyroidism
- Hypocalcemia
- Hypophosphatemia
- Low trauma fractures
- Muscle weakness
- Vitamin D deficiency
- "Waddling" gait

[a] T-score represents number of standard deviations below or above the mean bone mineral density for a healthy, sex- and race-matched, young adult (20–29 years) reference population; Z-score represents number of standard deviations below or above the mean bone mineral density for an age-, sex-, and race-matched reference population.

Table 50-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Osteoporosis and Osteomalacia[2]

- Alcoholism
- Anorexia nervosa
- End-organ failure and transplantation
- Endocrine disorders (e.g., hyperparathyroidism, Cushing syndrome, hyperthyroidism, growth hormone deficiency, acromegaly, male hypogonadism, hyperprolactinemia including drug-induced hyperprolactinemia, diabetes mellitus, vitamin D deficiency)
- Gastrointestinal disorders (e.g., celiac disease, inflammatory bowel disease, bariatric surgery)
- Genetic disorders (e.g., Ehlers–Danlos syndrome, hemochromatosis, Marfan syndrome, porphyria)
- Hematologic/oncologic disorders (e.g., multiple myeloma, sickle cell disease, thalassemia major, systemic mastocytosis)
- Idiopathic hypercalciuria
- Immobility
- Infectious diseases (e.g., human immunodeficiency virus)
- Neurologic disorders (e.g., spinal cord injury/immobilization, Parkinson disease, multiple sclerosis)
- Nutritional deficiencies (e.g., calcium, magnesium, vitamin D)
- Pulmonary disorders (e.g., chronic obstructive pulmonary disease)
- Rheumatologic disorders (e.g., rheumatoid arthritis, ankylosing spondylitis, systemic lupus erythematosus)
- Transplantation

Asymptomatic patients typically are identified through routine BMD testing, and T-scores and Z-scores are used to determine whether or not bone disease exists. The T-score represents the number of standard deviations below or above the mean BMD for a healthy, sex- and race-matched young adult (20–29 years) reference population. A Z-score represents the number of standard deviations below or above the mean BMD for an age-, sex-, and race-matched reference population.

Dual-energy x-ray absorptiometry measurements of the hip and spine are used to establish or confirm a diagnosis of osteoporosis.[60] For postmenopausal women and men 50 years of age or over, a normal BMD is defined as a T-score of −1 and above; low bone mass or osteopenia is defined as a T-score between −1 and −2.5; and osteoporosis is defined as a T-score at or below −2.5.[60] For premenopausal women and men younger than 50 years of age with a suspected secondary cause, a Z-score of −2 or below is considered "below the expected range for age" and is indicative of osteoporosis.[86] When any Z-score is −2 or worse, secondary causes of osteoporosis (including drug-induced) should be ruled out, regardless of age.

The decision to perform bone density assessment should be based on individual fracture risk and skeletal health. BMD testing is indicated in adults taking a medication (e.g., glucocorticoids in a daily dose of ≥5 mg of prednisone or equivalent for ≥3 months) associated with low bone mass or bone loss.[60,87] The WHO fracture risk assessment model incorporates various risk factors along with hip BMD results to assess an individual's risk of future fractures. This tool describes the probability of fracture in the next 10 years and can provide guidance regarding treatment.[87]

The National Osteoporosis Foundation and the International Society of Clinical Densitometry recommends BMD testing for adults taking medications such as glucocorticoids that are associated with bone loss. Central dual-energy x-ray absorptiometry screening should be performed as part of the treatment strategy for these patients. Most experts agree that a clinical diagnosis of osteoporosis can be made without further testing in any patient who has a suspected secondary cause for osteoporosis and presents with a low trauma fracture.

Suspicion of drug-induced osteoporosis is typically higher when the disease is identified in individuals in whom it would not typically be expected (e.g., men under age 50 or premenopausal women). However, drugs should always be suspected as a possible cause of osteoporosis or osteomalacia in any patient receiving agents associated with bone loss and fractures. Other secondary causes of osteoporosis to consider include lifestyle factors such as excessive alcohol consumption, genetic disorders, hypogonadal states, human immunodeficiency virus, endocrine disorders, gastrointestinal disorders, and hematologic disorders. Table 50-4 lists conditions to consider in the differential diagnosis of drug-induced osteoporosis.

There is no current consensus regarding what constitutes appropriate and cost-effective evaluation of patients with suspected secondary osteoporosis. In addition to a complete history and physical examination, the National Osteoporosis Foundation (NOF) recommends assessing liver enzymes, thyroid-stimulating hormone, parathyroid hormone, total testosterone and gonadotropin, serum 25-hydroxyvitamin D, and serum and urine calcium.[60] The American Association of Clinical Endocrinologists recommends a complete blood count and measuring serum calcium, phosphorus, total protein, albumin, creatinine, liver enzymes, alkaline phosphatase, electrolytes, and urinary calcium excretion.[88] Additional laboratory tests may be necessary, and their use will vary depending on the suspected cause.

Signs and symptoms of drug-induced osteomalacia often develop slowly, and the presentation is generally not different from that of patients with osteomalacia from other causes.[71] Typical symptoms include generalized bone pain and muscle weakness, which can lead to a characteristic waddling gait. Patients with osteomalacia may also present with fractures and with osteopenia or osteoporosis. Abnormal laboratory findings in these patients might include hypocalcemia, hypophosphatemia, hypovitaminosis D, and increased serum parathyroid hormone or alkaline phosphatase concentrations, or both.[71]

RISK FACTORS

Many patients with drug-induced osteoporosis have other risks that increase the likelihood of bone loss and fractures. It is frequently the combination of the drug and the underlying risks that lead to osteoporosis. General risk factors for the development of osteoporosis include potentially modifiable adverse lifestyle practices such as low calcium intake, consumption of three or more alcoholic beverages per day, smoking, and inadequate physical activity. Advanced age, female sex, history of falls or fractures (or both), low body weight or body-mass index, hypogonadism (postmenopausal status), and family history of fracture all significantly increase fracture risk and may or may not be modifiable. Several of these risk factors are included in the WHO Fracture Risk Assessment Model.

Several diseases and the drugs used in their treatment have been associated with adverse bone effects. It is often difficult to separate the effects of the drugs on bone remodeling from the effects of the disease state for which the drug is being used. For example, a systematic review identified that patients with chronic obstructive pulmonary disease (COPD) were at high risk for osteopenia and osteoporosis, with a reported prevalence ranging from 9% to 69% and 27% to 67%, respectively.[89] This review also found low body mass index correlates to osteoporosis and/or low BMD. Measures of body composition, disease severity, and the use of corticosteroids in COPD make it difficult to prove causality of these individual effects on bone health. Similarly, patients undergoing solid-organ transplantation are at high risk for osteoporosis due in part to the effects antirejection medications have on bone remodeling, even though the effect of the underlying organ failure on bone remodeling may be more important.

Certain patients are at an increased risk for drug-induced vitamin D deficiency and osteomalacia. Patients who are institutionalized, live in extreme northern latitudes, are elderly, have malabsorptive disease states, have cultural or religious beliefs that require full body coverage with clothing, or who belong to ethnic and racial groups with darkly pigmented skin are all at increased risk for low vitamin D concentrations.[90,91] The elderly are especially at risk because of a combination of factors including inadequate exposure to sunlight, a reduced skin conversion of 7-dehydrocholesterol to vitamin D_3, and impaired calcium absorption secondary to decreased intestinal responsiveness to vitamin D. Risk factors for drug-induced osteoporosis and osteomalacia are presented in **Table 50-5**.

Table 50-5 Risk Factors for Drug-Induced Osteoporosis and Osteomalacia[60,66]

- Advanced age
- Alcohol intake >2 servings per day
- Current cigarette smoking
- Female sex
- History of falls
- History of low trauma fracture in a parent or sibling
- Inadequate calcium intake
- Low body weight/body-mass index
- Low-trauma fracture as an adult
- Physical inactivity

Selected disease states associated with bone loss and fractures

- Chronic liver or kidney disease
- Chronic obstructive pulmonary disease
- Depression
- Diabetes mellitus (types 1 and 2)
- History of thyrotoxicosis
- Hypogonadism
- Inflammatory bowel disease
- Multiple sclerosis
- Rheumatoid arthritis
- Solid-organ transplant
- Vitamin D deficiency

Drug-specific risk factors

- Antiepileptic agents: Immobility, handicapped patients, combination of agents, higher doses, long-term use, factors that contribute to vitamin D deficiency such as darkly pigmented skin, institutionalization, limited sunlight exposure, malabsorptive states
- Heparin: High-dose, long-term
- Systemic glucocorticoids: Dose- and duration-dependent; higher cumulative exposure
- Thyroid hormone: Oversuppression of thyroid-stimulating hormone to <0.1 milli-international units/L
- Vitamin A: High doses (at least 2 times the recommended daily allowance)

MORBIDITY AND MORTALITY

Fractures are the most disconcerting consequence of drug-induced osteoporosis or osteomalacia. In 2000, there were an estimated 9 million new osteoporotic fractures worldwide, of which 1.6 million were at the hip, 1.7 million were at the forearm, and 1.4 million were clinical vertebral fractures.[92] Most of these fractures (51%) occurred in Europe and the Americas; the rest occurred in the Western Pacific region and Southeast Asia. Furthermore, one in three women over 50 years will experience osteoporotic fractures, as will one in five men over 50 years. By 2050, the worldwide incidence of hip fracture is projected to increase by 240% in women and 310% in men.[93] Most fractures in older adults are due in part to low bone mass, which can be drug-induced. Fractures can also impact morbidity by causing psychological symptoms, especially depression, reduced self-esteem, anxiety, fear, and anger as patients struggle with pain, physical limitations, and lifestyle and cosmetic changes.[60] Approximately 60% of patients with hip fracture lose their prefracture level of independence, which may strain interpersonal relationships and social roles for patients and their families. Furthermore, about 20% of patients with a hip fracture require long-term nursing home care.[1] Although many patients with fractures go on to full recovery, others may experience chronic pain, disability, and even death.

Hip fractures increase the risk of mortality within 1 year after the injury by 8–36% and are associated with a 2.5-fold increased risk of future fractures.[94,95] Mortality is also increased after vertebral fractures, which can cause back pain, height loss, and kyphosis.[60] The postural changes that occur with kyphosis may limit activity (e.g., bending and reaching). Vertebral fractures may result in restrictive lung disease and/or altered abdominal anatomy, which may lead to constipation, abdominal pain, distention, reduced appetite, and premature satiety. Vertebral fractures are also major predictors of future fractures with up to a 5-fold increased risk for subsequent vertebral fractures and a 2- to 3-fold increased risk for fractures at other sites.[60]

The exact incidence of morbidity and mortality secondary to drug-induced osteoporosis is not known. Glucocorticoids are the most common cause of drug-induced osteoporosis, and it is estimated that 0.2–0.5% of the general population receives systemic glucocorticoids and that 30–50% of patients receiving long-term glucocorticoid therapy will experience a fracture.[47,48]

Fracture risk increases in the first 3 months after glucocorticoid initiation and decreases after discontinuing glucocorticoid therapy; however, the risk appears never to return to baseline.[96]

PREVENTION

All persons starting or continuing therapy with a medication known to have bone-damaging effects should be assessed for the presence of other possible causes of and risk factors for bone loss and fracture. Exposure to potential culprit agents should be minimized by using the lowest dose and shortest treatment duration possible. Sometimes it is possible to substitute other drugs or routes of administration with similar efficacy but a lower risk profile. For example, inhaled glucocorticoids at usual doses are not thought to cause appreciable bone loss as compared to systemic glucocorticoids and should be used preferentially whenever possible in patients with respiratory diseases such as COPD and asthma.[96] Although data are inconclusive regarding the effects of inhaled corticosteroids on bone density, a trend toward decreased BMD and increased fracture risk in patients using long-term moderate- to high-dose inhaled corticosteroids has been demonstrated.[96,97] In patients who have undergone transplantation, use of immunosuppressive agents such as rapamycin, tacrolimus, or mycophenolate mofetil, which are less likely to cause osteoporosis than cyclosporine, may be considered. Newer antiepileptic drugs such as lamotrigine, topiramate, and levetiracetam are less likely than phenytoin, carbamazepine, or phenobarbital to cause osteomalacia and osteoporosis. Ritonavir, a protease inhibitor often used to boost antiretroviral therapy, has been shown to inhibit osteoclast maturation and function leading to reduced bone resorption and may be a bone-sparing alternative for patients with human immunodeficiency virus receiving highly active antiretroviral therapy.[98,99] Raltegravir or abacavir may be better options than tenofovir disoproxil for patients at high risk of osteopenia or osteoporosis.[11,100] Consideration of these types of lower-risk alternative therapies is especially important in patients with multiple underlying risk factors for bone loss and fractures.

An important first step in preventing drug-induced osteoporosis is educating the patient regarding a bone-healthy lifestyle. Patients should be counseled on smoking cessation and limiting alcohol and caffeine consumption.[60] Regular weight-bearing and muscle-strengthening exercises should be encouraged to help maintain bone mass and reduce the risk of falls. Other fall-prevention strategies should be discussed with patients at high risk for falling. Methods to achieve adequate intake of calcium and vitamin D should be reviewed. **Table 50-6** describes approaches to help prevent drug-induced osteoporosis and osteomalacia.

Table 50-6 Approaches to Help Prevent Drug-Induced Osteoporosis and Osteomalacia[60,69,91,101,102]

General strategies

- Identify and manage other secondary causes and risk factors
- Use an alternative therapy with a lower risk, if possible
- Use therapy for the shortest time possible and at the lowest effective dose

Drug-specific

- 2,000–4,000 units/day of oral cholecalciferol (vitamin D_3) or 50,000 units of oral ergocalciferol (vitamin D_2) every 1–4 weeks may be needed in patients receiving enzyme-inducing antiepileptic drugs
- Consider low-molecular-weight heparin instead of unfractionated heparin in patients who require long-term anticoagulation and in whom warfarin is contraindicated (e.g., pregnancy)
- Use inhaled glucocorticoids in place of systemic drugs when possible for the treatment of respiratory diseases such as asthma and chronic obstructive pulmonary disease
- Use H_2 blockers instead of proton pump inhibitor for gastroesophageal reflux disease when possible in patients taking a bisphosphonate
- Use multivitamin supplements that contain no more than the recommended dietary allowance of 700 mcg/day (adult female) to 900 mcg/day vitamin A; upper tolerable limit (adults) = 3,000 mcg/day
- Use steroid-sparing therapies for rheumatoid arthritis, inflammatory bowel disease, and organ transplantation when possible

Bone-healthy lifestyle

- Adequate calcium intake[a]:

Age (yr)	Recommendation
1–3	500 mg
4–8	800 mg
9–18	1,300 mg
19–49	1,000 mg
≥50	1,200 mg

- Adequate vitamin D intake[a,b]:

Age (yr)	Recommendation
1–18	400 units
19–49	400–800 units
≥50	800–1,000 units
Pregnant or lactating	400–800 units

- Alcohol intake ≤1 serving/day (women) and ≤2 servings/day (men)
- Caffeine intake ≤2 servings/day
- Reduce fall risk
- Resistance/strengthening exercises (free weights, resistance bands, weight machines) for 20–30 min/day, 2–3 days/wk
- Smoking cessation
- Weight-bearing exercise of moderate intensity for at least 30 min most days of the week

---

[a] 1,500 mg of calcium and 800 international units of vitamin D are recommended in patients receiving glucocorticoids at a dose of ≥5 mg prednisone or equivalent for ≥3 months.

[b] Higher intake of vitamin D may be needed in patients with vitamin D concentrations in the deficient range (25-hydroxy vitamin D concentration <12 ng/mL).

MANAGEMENT

Treatment strategies for drug-induced osteoporosis or osteomalacia are similar to those used in the management of primary osteoporosis and osteomalacia and are presented in Table 50-7.

Table 50-7 Approaches to the Treatment of Drug-Induced Osteoporosis

Antiresorptive Therapy	Fracture Reduction—Key Clinical Trials
BISPHOSPHONATES	
Alendronate[a] (10 mg orally daily or 70 mg orally weekly)[103,104]	Vertebral: RR 0.45; 95% CI 0.27–0.72; $p = 0.001$ Hip: RR 0.49; 95% CI 0.23–0.99; $p = 0.047$ Glucocorticoid-induced osteoporosis (vertebral fractures): 0.7% versus 6.8% ($p = 0.026$) alendronate-treated versus placebo, respectively.
Ibandronate (2.5 mg daily or 150 mg orally monthly or 3 mg IV every 3 months)[105]	Vertebral: RR 0.38; 95% CI 0.25–0.59; $p = 0.0001$ Hip: NS
Risedronate[a] (5 mg orally daily or 35 mg orally weekly or 150 mg orally monthly)[106-108]	Vertebral: RR 0.59; 95% CI 0.43–0.82; $p = 0.003$ Hip: RR 0.7; 95% CI 0.6–0.9; $p = 0.02$ Glucocorticoid-induced osteoporosis (vertebral fractures): 16% versus 5% ($p = 0.01$)
Zoledronic acid[a] (5 mg IV once yearly)[109]	Vertebral: RR 0.30; 95% CI 0.24–0.38; $p < 0.001$ Hip: RR 0.59; 95% CI 0.42–0.83; $p = 0.002$
MONOCLONAL ANTIBODY	
Denosumab (60 mg sub-Q every 6 months)[110,111]	Vertebral: RR 0.38; 95% CI 0.19–0.78; $p = 0.006$ Hip: No data
SELECTIVE ESTROGEN RECEPTOR MODULATORS	
Raloxifene (60 mg/day)[112]	Vertebral: RR 0.7; 95% CI 0.5–0.8 Hip: NS
OTHER	
Calcitonin nasal (200 international units/day)[113]	Vertebral: RR 0.67; 95% CI 0.47–0.97; $p = 0.03$ Hip: NS
ANABOLIC THERAPY	
Teriparatide (20 mcg sub-Q daily)[104,114-116]	Vertebral: RR 0.35; 95% CI 0.22–0.55; $p \leq 0.001$ Hip: NS Glucocorticoid-induced osteoporosis (vertebral fractures, teriparatide versus alendronate): 0.6% versus 6.1% ($p = 0.004$)

CI = confidence interval, IV = intravenous, NS = not significant, RR = relative risk, sub-Q = subcutaneous.

[a]Approved by the U.S. Food and Drug Administration for glucocorticoid-induced osteoporosis.

When a drug is believed to be contributing to bone loss, discontinuation of the suspected agent or a reduction in dose, when possible, is an important first step. Although specific guidelines exist for some medications known to cause secondary osteoporosis (e.g., glucocorticoids), even in the absence of specific guidelines, most experts agree that bisphosphonates and other approved agents for primary osteoporosis are reasonable treatment options for patients with drug-induced osteoporosis.[69] In all cases, counseling patients about the importance of calcium, vitamin D, exercise, and other healthy bone lifestyle practices should be incorporated as a part of the treatment plan.[60]

The NOF recommends consideration of treatment for postmenopausal women and men age 50 years and older with the following presentation(s)[60]:

- A hip or vertebral (clinical or found on vertebral imaging) fracture
- T-score ≤−2.5 at the femoral neck, total hip, or lumbar spine after appropriate evaluation to exclude secondary causes
- Low bone mass (T-score between −1 and −2.5 at the femoral neck or spine) and a 10-year probability of a hip fracture ≥3% or a 10-year probability of a major osteoporosis-related fracture ≥20% based on the U.S.-adapted WHO algorithm

Unfortunately, these intervention thresholds do not take into account the added risks associated with the use of drugs known to predispose to osteoporosis or osteomalacia. The FRAX fracture risk assessment tool may be helpful to determine appropriate treatment; however, it should be noted that the model is constructed from population-based cohorts with a limited age range, specifically women and men >50 years of age.[87] The FRAX tool was not intended for younger women and men. Prophylactic treatment with a bisphosphonate should be carefully considered in patients at risk for drug-induced osteoporosis or osteomalacia when the T-score is below −1 at the spine or hip.[69]

Alendronate, risedronate, zoledronic acid, and teriparatide are approved for use in the United States for glucocorticoid-induced osteoporosis; teripartide appears to be the most effective of these agents.[115,116] Ibandronate and denosumab are not approved for this indication, but have been shown to significantly reduce fractures in patients with osteoporosis.[105,111] Other medications that may be considered for the treatment of drug-induced osteoporosis include calcitonin and raloxifene (in women); however, fracture prevention data with these agents are not as strong as for other treatment options.[112,113]

Treatment strategies for drug-induced osteomalacia primarily focus on the causative agent, the vitamin D deficiency, or both. When possible, the culprit drug should be discontinued and vitamin D therapy initiated if concentrations are found to be insufficient.[71] Vitamin D is considered sufficient if the serum 25-hydroxyvitamin D concentration is ≥30 ng/mL.[91] High-dose vitamin D supplementation may be needed if deficiency is present. A cost-effective method of correcting vitamin D deficiency and maintaining adequate concentrations is to give patients 50,000 international units of vitamin D_2 orally once a week for 8 weeks followed by 50,000 units of vitamin D_2 every 2–4 weeks thereafter.[91] In addition, correction of hypophosphatemia may be necessary and should be considered in patients with drug-induced osteomalacia. Bisphosphonates and other approved agents for primary osteoporosis are also reasonable treatment options for patients with osteomalacia and a high risk or history of fracture.

INFORMATION FOR PATIENTS

Patients receiving medications that may cause drug-induced osteoporosis or osteomalacia should be made aware of the potential and extent of risk caused by the given agent(s). Patients should be encouraged to engage in lifestyle activities that promote bone health, such as weight-bearing exercise, avoidance of tobacco and excessive alcohol and caffeine consumption, consumption of adequate calcium and vitamin D, and participation in fall risk assessments. Healthcare providers should guide their patients in making appropriate decisions about when to perform BMD testing and when treatment may be necessary to prevent or treat drug-induced osteoporosis or osteomalacia.

If treatment with a bisphosphonate is warranted, the patient's ability to swallow the medication, renal function, and calcium and vitamin D status should be evaluated. When an oral bisphosphonate is to be prescribed, the patient should be counseled regarding proper use. Bisphosphonates should be taken 30 minutes (60 minutes for ibandronate) before the first food or drink of the day. The dose should be swallowed with the patient in an upright position and taken with a full glass of water. Patients should not lie down for 30 minutes after taking the medication. Bisphosphonates should not be taken with any other medication. Premenopausal women should be made aware that bisphosphonates are pregnancy category C/D and contraceptive measures should be recommended as appropriate. Zoledronic acid and ibandronate have intravenous formulations for patients who have difficulty swallowing or remembering to take their medication weekly.

CHAPTER 51

Gout and Hyperuricemia

Jasmine D. Gonzalvo

Gout is an inflammatory disease induced by monosodium urate crystals that precipitate in joints and soft tissues, causing an intense inflammatory reaction. A number of drugs may alter urate excretion or increase uric acid production and predispose patients to hyperuricemia with or without gout. Hyperuricemia, defined as a serum urate concentration >6.8–7 mg/dL, may contribute to renal, cardiovascular, and metabolic risk. In general, pharmacotherapy is not recommended for patients with asymptomatic hyperuricemia.[1,2]

CAUSATIVE AGENTS

Agents implicated in drug-induced gout and hyperuricemia are listed in **Table 51-1**.[1-84] Reports suggest a variety of contributory mechanisms for each of these agents' ability to increase uric acid concentrations. Hyperuricemia, rather than acute attacks or an established diagnosis of gout, is more commonly associated with each of these agents.

EPIDEMIOLOGY

In the United States, gout occurs in approximately 3.9% of the general population and is more common in men.[3] A high intake of red meat or alcohol, older age, chronic kidney disease, and the presence of the metabolic syndrome (hypertension, diabetes, dyslipidemia, and truncal obesity) are all recognized risk factors for the development of hyperuricemia and gout.[1] Although the prevalence and incidence of gout have risen over several decades, the prevalence and incidence of drug-induced hyperuricemia and gout are not well documented. The incidence of drug-induced gout and hyperuricemia varies greatly among the causative agents.

MECHANISMS

Several mechanisms for drug-induced hyperuricemia and gout have been identified (**Table 51-2**). The most common mechanism is interference with uric acid excretion leading to accumulation in serum. The urate–anion exchanger, urate transporter-1 (URAT1), at the apical brush-border membrane of renal proximal tubular epithelial cells plays a role in uric acid reabsorption and can predispose to drug-induced hyperuricemia and gout. Drugs that cause cellular death (e.g., antitumor drugs) may induce gout by dramatically increasing uric acid concentrations resulting from increased protein catabolism.

Table 51-1 Agents Implicated in Drug-Induced Gout and Hyperuricemia

Drug	Incidence	Level of Evidence[a]
Allopurinol[53]	NK	B
Aspirin—low dose[9]	NK	B
Cyclosporine[1,10-24]	1–10%	B
Cytotoxic agents[13,25,53]	NK	B
Diuretics[35-40]	NK	A
Ethambutol[53-59]	66%	A
Ethanol[60-65,67]	1.5%	B
Febuxostat[5,6,53]	NK	B
Levodopa[68-71]	48.8%	B
Nicotinic acid[53]	NK	B
Pyrazinamide[30,53,76,77]	NK	C

Tacrolimus[78-81]	42%	B
Teriparatide[83,84]	3%	B
Uricosuric agents[5,6,53]	NK	B

NK = not known.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials;

Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

Table 51-2 Mechanisms of Drug-Induced Gout and Hyperuricemia

Drug	Mechanism
Allopurinol[53]	Not well elucidated
Aspirin—low dose[9,30]	Decreases renal uric acid excretion
Cyclosporine[10,30]	Increases renal tubular uric acid reabsorption, particularly through decreased glomerular filtration, increased blood pressure, and interstitial nephropathy
Cytotoxic agents[53]	Release large amounts of uric acid following rapid and frequent cell turnover
Diuretics[30,53]	Increase renal tubular reabsorption of uric acid
Ethambutol[30]	Decreases renal uric acid excretion
Ethanol[60-64]	Decreases uric acid excretion through competition with lactic acid; increases uric acid production through rapid hepatic breakdown of adenosine triphosphate or antidiuretic hormone inhibition and transient dehydration
Febuxostat[53]	Not well elucidated
Levodopa[68-79]	Not well elucidated
Nicotinic acid[30]	Stimulates absorption of luminal urate through urate transporter-1
Pyrazinamide[30]	Stimulates absorption of luminal urate through urate transporter-1
Tacrolimus[30]	Increases renal tubular uric acid reabsorption, particularly through decreased glomerular filtration, increased blood pressure, and interstitial nephropathy
Teriparatide[100]	Likely related to increased serum concentrations of parathyroid hormone
Uricosuric agents[53]	Not well elucidated

ALLOPURINOL, FEBUXOSTAT, AND URICOSURIC AGENTS

Although the xanthine oxidase inhibitors allopurinol and febuxostat and uricosuric agents such as probenecid and fenofibrate have been effective in the prevention of gout attacks, these medications paradoxically induce attacks in some individuals soon after initiation of urate-lowering therapy.[3] These attacks may be due to remodeling of articular urate crystal deposits following rapid and substantial lowering of urate concentrations.[3] It is recommended that allopurinol be started at a dose of no greater than 100 mg daily and that the daily dose be increased by 100 mg every 2–5 weeks to help avoid a rapid drop in serum urate concentrations sometimes associated with precipitation of acute gout. For patients with stage 4 or worse chronic kidney disease, the dose of allopurinol should start at 50 mg daily.[3] Febuxostat should be initiated at 40 mg daily and increased to 80 mg daily if serum uric concentrations do not reach <6 mg/dL after 2 weeks of treatment.[4] A similar titration strategy should be used when initiating therapy with uricosuric agents. Individuals treated with these agents should maintain adequate hydration, and therapy should begin with low doses and the dose increased slowly over several weeks to avoid excessive uricosuria and possible kidney stone formation. Although fenofibrate has demonstrated benefit for the treatment of hyperuricemia through its uricosuric properties, it has not been associated with precipitation of acute gout attacks.[5-7]

Patients receiving long-term treatment with allopurinol or uricosuric agents are also at risk for gout with sporadic medication adherence. Extra efforts to thoroughly educate patients as to why the prescribed medication is beneficial and important and to encourage adherence to prescribed regimens is advised.

ASPIRIN—LOW DOSE

In doses <2 g daily, aspirin has been shown to cause uric acid retention and hyperuricemia due to *trans*-stimulation of URAT1.[8] Higher doses of aspirin are uricosuric due to the *cis*-inhibition of URAT1.[8] The effect of minidose aspirin on urate excretion was examined in 49 elderly patients.[9] A 6% increase in serum urate concentration and a 23% decrease in urate clearance was seen during the first week of aspirin therapy, but these values returned to baseline by week 3, even though the dose of aspirin was increased from 75–325 mg daily. Urate clearance and creatinine clearance were reduced in parallel. The hyperuricemic effects of aspirin were more pronounced in patients also taking diuretics and those with hypoalbuminemia.[9] In a large, prospective case-crossover study in a population of patients diagnosed with gout, aspirin daily doses of <325 mg were associated with an almost twofold increased risk of recurrent attacks of gout as compared to daily aspirin doses >325 mg.[8] However, this study examined aspirin use only in the prior 2 days and did not follow patients for a longer time period to identify longer-term trends.

Most clinicians would not withhold low-dose aspirin therapy in patients at high risk for cardiovascular disease who also have gout, as the cardiovascular benefits likely outweigh the risk of an increased frequency of gout attacks. Thorough patient education regarding the risks and benefits of low-dose aspirin therapy along with regular serum urate monitoring may be warranted in patients with pre-existing gout. If the decision is made to initiate treatment for hyperuricemia or gout in patients receiving low-dose aspirin, xanthine oxidase inhibitors or uricosuric agents may be considered.[8]

CYCLOSPORINE

Cyclosporine, an immunosuppressive agent commonly used to prevent rejection in patients with solid organ transplants, is associated with hyperuricemia. This effect is due to alteration of renal tubular handling of uric acid leading to decreased urate excretion.[10] It is estimated that hyperuricemia develops in up to 80% of patients receiving cyclosporine.[1,11] Gout has been reported to develop in 4–24% of patients who have undergone transplantation and are receiving cyclosporine.[11] Burack and colleagues reported hyperuricemia in 72% of males and 81% of females treated with cyclosporine following heart or heart–lung transplantation.[10] In another study, 42% of patients receiving cyclosporine required allopurinol therapy for hyperuricemia as compared with only 9% of those who did not receive cyclosporine.[12]

Although hyperuricemia appears to be quite common in patients who have undergone renal transplantation, nephrolithiasis is unusual and renal failure is extremely rare. Nonetheless, the American Society of Nephrology recommends measuring the serum urate concentration within the first 2–3 months of cyclosporine therapy.[13-24]

CYTOTOXIC AGENTS

Drug-induced hyperuricemia associated with cytotoxic drugs can lead to significant renal compromise. Cytotoxic drugs may induce tumor lysis syndrome, a condition that occurs following chemotherapy with a high cell kill. Tumors most likely to be associated with tumor lysis syndrome include mature B-cell and T-cell lymphomas such as Burkitt lymphoma, lymphoblastic lymphoma, and some acute leukemias, although breast and lung tumors have also been implicated.[25] The rapid and frequent cell turnover associated with cytotoxic agents can result in the release of intracellular contents into the blood, including large quantities of potassium, phosphorus, and uric acid. Uric acid nephropathy develops as a result of the precipitation of uric acid crystals in the kidney. High-risk patients routinely receive prophylactic therapy for tumor lysis syndrome consisting of pretreatment with hydration, urine alkalinization, and allopurinol. Rasburicase can be considered as an alternative to allopurinol. Advantages of rasburicase include a faster onset of action and increased ability to lower uric acid as compared with oral allopurinol. Disadvantages include hypersensitivity reactions and hemolytic anemia, although these are rare.[13]

DIURETICS

Diuretics, commonly used for the treatment of hypertension, increase serum urate concentrations in a dose-dependent manner by directly increasing proximal tubular reabsorption of uric acid and through volume depletion and resultant increased urate reabsorption by the proximal tubule. Research has explored pharmacogenomic associations with diuretic-induced hyperuricemia, although definitive conclusions have yet to be determined.[26,27] Hypertension itself has been independently associated with the development of gout.[28,29] However, a connection between use of diuretics and an increased risk of gout in hypertensive patients is controversial.[30-34] In a trial involving 3,693 patients with hypertension who were treated with thiazide diuretics, investigators found an association between diuretic therapy and elevated serum uric acid concentrations but concluded that these elevations did not correlate with kidney damage or significant increases in the frequency of gout.[35] A case-control study reported no relationship between the use of diuretics and an increased risk of gout.[36] Conversely, Choi and colleagues[37] have suggested that diuretics increase the relative risk of gout by almost 80% with an absolute incidence of gout in individuals treated with diuretics around 3%. Moreover, a study of 197 patients who had experienced a gout attack within the past year revealed a significantly increased risk of recurrent gout attacks attributed to the use of thiazide diuretics.[38] A retrospective population-based case-control study in a population of 91,350 patients with a first-time diagnosis of gout found an increased risk of gout with the use of loop, thiazide, and thiazide-like diuretics but not with potassium-sparing diuretics.[39]

Diuretics, along with angiotensin-converting enzyme inhibitors (ACEIs), angiotensin II receptor blockers (ARBs), and calcium channel blockers, are considered to be preferred drugs for the initial treatment of hypertension as they are highly effective and work well in combination with other classes of antihypertensives.[40] Concern about the possible precipitation of gout should not keep patients with hypertension and asymptomatic hyperuricemia from receiving diuretic therapy, although caution should be used with these agents in patients with gout. Of note, gout is unlikely to occur with hydrochlorothiazide doses <50 mg daily or chlorthalidone doses <25 mg daily.[40] Some evidence also exists suggesting that ACEIs, β-blockers, and nonlosartan ARBs are associated with an increased risk of gout.[28,39,41,42] Losartan and calcium channel blockers have been associated with a decreased risk of developing gout.[28,39,43-49]

ETHAMBUTOL

Ethambutol, an antitubercular agent, has been shown to decrease renal uric acid excretion.[30,50] Increased uric acid levels have been noted as early as 24 hours and as late as 90 days after initiation of ethambutol treatment.[51] In one study, investigators evaluated 131 patients treated for active tuberculosis. One group received ethambutol, streptomycin, and isoniazid, while the control group received streptomycin, isoniazid, and thiacetazone. Increased serum uric acid concentrations were found in 66% of patients in the ethambutol group, whereas patients in the control group experienced no significant change.[52] Of note, only two cases of gout were reported in the trial.[53,54] A second study of 14 patients with tuberculosis and a history of gout also documented an increase in serum uric acid concentrations after ethambutol treatment.[55] However, none of the patients progressed to have acute attacks of gout. Louthrenoo and colleagues[50] also found a minor, reversible increase in uric acid levels in a small population of 16 patients with tuberculosis treated with ethambutol or pyrazinamide. Ethambutol must typically be used in combination with pyrazinamide to effectively treat tuberculosis. Close monitoring for signs and symptoms of gout is warranted in these patients because the concomitant use of these two agents may impart greater risk than the use of either agent alone.[54,56-59]

ETHANOL

Gout has been noted in association with excess ethanol consumption for centuries. Touted as “the disease of kings,” gout was first reported after royal feasts at which large amounts of ethanol and meats were consumed. It is now known that ethanol can lead to hyperuricemia through both decreased uric acid excretion and increased uric acid production.[60-64] When consumed in excess, ethanol causes the rapid hepatic breakdown of adenosine triphosphate and increases urate production. Excessive ethanol consumption may also induce lactic acidosis. Lactic acid competes with urate for excretion through the kidney. Alcohol-induced inhibition of antidiuretic hormone may lead to transient dehydration, which can temporarily increase serum uric acid concentrations.[62] Secondarily, excess ethanol consumption may lead to long-term obesity, which has been associated with underexcretion of uric acid. A correlation between beer consumption and relative risk for developing hyperuricemia has been established, although moderate wine consumption does not appear to increase the risk of gout.[65,66] A related prospective study from Choi and colleagues[64] recognized alcohol consumption as an independent risk factor for gout. Patients with gout should be advised to limit alcohol consumption, especially beer.[3]

LEVODOPA

Levodopa use has been associated with an increase in serum uric acid concentration.[68-70] In one retrospective review, 48% of the 86 patients treated with an average of 4.3 g of levodopa per day developed elevated serum uric acid concentrations. The incidence of clinically evident gout was not reported.[71] Conversely, in a small, case-control study by Andreadou and colleagues,[72] an inverse relationship between levodopa dose and uric acid levels was found. Patients with concurrent diagnoses of gout and Parkinson disease treated with levodopa should be monitored for symptoms of gout. Risks and benefits should be evaluated when determining the most appropriate treatment for patients who have both gout and Parkinson disease. When levodopa is determined to be the drug of choice, the risks and benefits of prophylactic therapy for gout should also be evaluated.

NICOTINIC ACID

Nicotinic acid, a drug used to treat dyslipidemia, stimulates the absorption of uric acid through URAT1, which is located at the apical brush-border membrane of renal proximal tubular epithelial cells and is responsible for local uric acid reabsorption. Increased nicotinic acid concentrations stimulate URAT1-dependent anion exchange with uric acid, which may result in hyperuricemia.[30]

One study reported a decrease in uric acid excretion of up to 75% when nicotinic acid was given in doses up to 4.5 g daily (a much higher dose than usually tolerated by patients because of flushing).[53] Another study reported that nicotinic acid in doses of 1 g daily reduced the excretion of uric acid by 62%.[53] Serum uric acid levels may increase by 5–15% in patients receiving nicotinic acid, but for most patients these elevations are clinically inconsequential.[73] Depending on the primary lipid target, multiple classes of medications may be substituted to achieve desired effects while reducing the risk of drug-induced hyperuricemia and gout. When possible, patients with a predisposition for gout should be maintained on agents other than niacin to decrease cardiovascular risk.

PYRAZINAMIDE

Pyrazinamide, a drug chemically related to nicotinic acid, is primarily indicated for the treatment of tuberculosis. Like nicotinic acid, pyrazinamide stimulates the absorption of uric acid through the urate–anion exchanger URAT1.

A major metabolite of pyrazinamide, pyrazinoic acid, inhibits the renal tubular secretion of uric acid also contributing to hyperuricemia.[74] As many as 43–100% of individuals treated with pyrazinamide, alone or in combination, experience hyperuricemia.[74] One retrospective epidemiological survey of 226 patients treated with pyrazinamide at an average dose of 1.18 g daily found peak uric acid levels between 10–11.9 mg/dL in males and 8–9.9 mg/dL in females, although, no acute attacks of gout occurred.[75] Patients treated with pyrazinamide must be monitored for the development of gout and, because adherence to multiple drug therapy is a significant concern with tuberculosis treatment, attacks must be managed appropriately so that antitubercular therapy can continue uninterrupted.[76,77]

TACROLIMUS

Limited conclusive data exist regarding the potential for hyperuricemia in patients treated with tacrolimus, a calcineurin inhibitor associated with impaired uric acid excretion.[78] A retrospective medical record review of recipients of liver transplants revealed that 42% of 43 patients treated with tacrolimus experienced hyperuricemia.[79] Similarly, a study comparing cyclosporine and tacrolimus in stable recipients of renal transplants found significant elevations in serum uric acid concentrations for both groups.[80] In addition, switching patients from cyclosporine to tacrolimus was not associated with a significant decrease in uric acid concentrations, although this approach had previously been proposed as a method to control cyclosporine-induced hyperuricemia.[81] Switching from a twice daily to a once daily formulation of tacrolimus also did not result in an improvement in tacrolimus-induced hyperuricemia.[82]

TERIPARATIDE

The parathyroid analog hormone teriparatide has been associated with dose-dependent elevations of uric acid.[83] Increases in serum uric acid concentration to above 9 mg/dL have been associated with doses ranging from 20 to 40 mcg daily.[83,84] To date, acute gout attacks have not been associated with teriparatide therapy; therefore, increased monitoring and prophylactic therapy are not warranted in most cases.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Signs and symptoms associated with drug-induced gout and hyperuricemia are listed in **Table 51-3**. The clinical presentation of drug-induced gout does not differ from that of gout associated with other causes. A patient presenting with gout should have a careful medication history taken to identify drugs that could be contributing to the disease. Patients with acute gout present with pain, swelling, and erythema, often involving just one or a few joints. An increased skin temperature is often noted over the affected joints and is associated with the inflammation. The onset of symptoms is abrupt in most patients. Acute attacks commonly occur overnight, as the affected joint space becomes saturated with monosodium urate following water reabsorption at the site.

Table 51-3 Signs and Symptoms Associated with Drug-Induced Gout and Hyperuricemia[96,101,102]

- Abrupt onset of attacks, usually lasting 5–10 days
- Asymmetric swelling within a joint on radiograph
- Involvement of one or more joints
- Joint fluid culture negative for organisms during attack
- Pain, erythema, swelling over joints
- Subcortical cysts without erosions on radiograph
- Symptom presentation at night
- Tophi

Unlike most other inflammatory arthritic conditions, most patients have no symptoms between attacks. This characteristic can be useful in differentiating gout from other arthritic conditions. Some patients may have involvement of associated tendons and present with more diffuse swelling, a condition called tenosynovitis. Over a period of days, sloughing of superficial skin layers may occur and this is associated with intense inflammation. The most frequently involved joint is the first metatarsal joint at the base of the first toe (gouty inflammation in this location is sometimes called podagra), although any joint may be affected. Distribution is more common in the distal portion of the lower extremities. Extreme pain over the affected joint is usually noted. Characteristically, patients report pain so severe that they do not wear shoes and cannot even tolerate the weight of bedcovers over the involved joint. Pain associated with minor stimuli is called allodynia.

Gout may present at any age, but the incidence peaks between the ages of 50 and 70 for men and between the ages of 50 and 90 for women. Earlier presentation is more likely to be associated with enzyme defects, renal disease, drugs, or toxins. Initially, patients typically experience rare, intermittent attacks involving one or a few joints. Over time, attacks may become more frequent and are more likely to be polyarticular. Eventually, patients may have a chronic, polyarticular arthritis, which may be difficult to distinguish from rheumatoid arthritis.

A key diagnostic finding that occurs in some patients is the presence of gouty tophi, which are subcutaneous deposits of uric acid in a nodule. These may occur anywhere, but are frequently found on fingers, elbows, and ankles and over the metatarsal joints. The outer helix of the ear may also be involved. Tophi are painless and may have a characteristic yellow color. In some cases they drain chalky white material, which is found to contain uric acid crystals when examined microscopically under polarized light. Other diseases, such as rheumatoid arthritis, which may cause rheumatoid nodules, and hyperlipidemia, which may cause xanthomas, should be considered in the differential diagnosis of patients with nodules (**Table 51-4**). Needle aspiration is a fairly simple test that may be performed to assist in differentiation. In most patients, gout is recognized long before the development of tophi, and appropriate treatment to lower serum uric acid concentrations prevents the development of these lesions.

Table 51-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Gout and Hyperuricemia[101,102]

- Cellulitis
- Fractures
- Infectious arthritis
- Palindromic rheumatism
- Pseudogout (calcium pyrophosphate deposition disease)
- Rheumatoid arthritis

A definitive diagnosis of gout may be made by the identification of intracellular uric acid crystals in synovial fluid neutrophils obtained on aspiration of an inflamed joint. Examination under a polarized light microscope is necessary to properly identify these crystals. Measurement of serum uric acid concentration may be of some value, although patients can have normal serum concentrations during acute attacks.[85] In the absence of crystal diagnosis, the presence of the following criteria permits a presumptive diagnosis: (1) hyperuricemia, (2) history of acute attacks of arthritis with asymptomatic periods between attacks, and (3) the ability of colchicine or nonsteroidal anti-inflammatory drugs (NSAIDs) to abort an attack. Historically, the criteria for the accurate classification of gout have lacked specificity and sensitivity. With the advent of advanced imaging techniques, in combination with other subjective and objective signs and symptoms, the classification of gout has become more standardized, specific, and sensitive. **Table 51-5** outlines the American College of Rheumatology/European League Against Rheumatism collaborative initiative classification criteria for gout. A cumulative score ≥8 using this tool is consistent with gout.[86]

Other potential causes of episodic arthritis must also be considered in evaluating patients for gout. Pseudogout is a disease caused by calcium pyrophosphate deposition and may be the most difficult to differentiate from gout. Calcium pyrophosphate crystals have morphology and polarizing characteristics that are different from those of uric acid crystals, so analysis of synovial fluid may be the best method to differentiate between gout and pseudogout. The presence of calcification of synovial cartilage (chondrocalcinosis) on a radiograph may also be helpful in differentiation, as this is found in patients with pseudogout but not gout. Septic arthritis, cellulitis, fractures, and a rare condition called palindromic rheumatism are other medical problems that may mimic gout and should be considered in the differential diagnosis.

Table 51-5 The American College of Rheumatology/European League Against Rheumatism Gout Classification Criteria[86,a]

	Categories	**Score**
Step 1: Entry criterion (only apply criteria in Step 3 to those meeting this entry criterion	At least one episode of swelling, pain, or tenderness in a peripheral joint or bursa	
Step 2: Sufficient criterion (if met, can classify as gout without applying criteria below)	Presence of monosodium urate monohydrate crystals in a symptomatic joint or bursa (i.e., in synovial fluid) or tophus	
Step 3: Criteria (below) to be used if sufficient criterion (Step 2) are not met:		
CLINICAL		
Pattern of joint/bursa involvement during symptomatic episode(s) ever[b]	Ankle or mid-foot (as part of monoarticular or oligoarticular episode without involvement of the first metatarsophalangeal joint)	1
	Involvement of the first metatarsophalangeal joint (as part of monoarticular or oligoarticular episode)	2
Characteristics of symptomatic episode(s) ever • Erythema overlying affected joint (patient reported or physician observed) • Can't bear touch or pressure to affected joint • Great difficulty with walking or inability to use affected joint	One characteristic Two characteristics Three characteristics	1 2 3
Time course of episode(s) ever Presence (ever) of ≥2, irrespective of anti-inflammatory treatment: • Time to maximal pain <24 hours • Resolution of symptoms in ≤14 days	One typical episode Recurrent typical episodes	1 2

• Complete resolution (to baseline) level between symptomatic episodes		
Clinical evidence of tophus Draining or chalk-like substance nodule under transparent skin, often with overlying vascularity, located in typical locations: joints, ears, olecranon bursae, finger pads, tendons (e.g., Achilles)	Present	4
Laboratory		
Serum urate: Measured by the uricase method Ideally should be scored at a time when the patient was not receiving urate-lowering treatment and it was >4 weeks from the start of an episode (i.e., during the intercritical period); if practicable, retest under those conditions; the highest value irrespective of timing should be scored	• <4 mg/dL[c] • 6 to <8 mg/dL • 8 to <10 mg/dL • ≥10 mg/dL	−4 2 3 4
Synovial fluid analysis of a symptomatic joint or bursa (should be assessed by a trained observer)[d]	Monosodium urate crystal negative	−2
Imaging[e]		
Imaging evidence of urate deposition in symptomatic joint or bursa: ultrasound evidence of double-contour sign[f] or dual energy computed tomography scanner demonstrating urate deposition[g]	Present (either modality)	4
Imaging evidence of gout-related joint damage: conventional radiography of the hands and/or feet demonstrates at least one erosion[h]	Present	4

[a] A web-based calculator can be accessed at http://goutclassificationcalculator.auckland.ac.nz, and through the American College of Rheumatology (ACR) and European League Against Rheumatism (EULAR) websites.

[b] Symptomatic episodes are periods of symptoms that include any swelling, pain, and/or tenderness in a peripheral joint or bursa.

[c] If serum urate level is <4 mg/dL (<0.24 mmol/L), subtract 4 points; if serum urate level is ≥4–6 mg/dL (≥0.24 – <0.36 mmol/L), score this item as 0.

[d] If polarizing microscopy of synovial fluid from a symptomatic joint or bursa by a trained examiner fails to show monosodium urate monohydrate (MSU) crystals, subtract 2 points. If synovial fluid was not assessed, score this item as 0.

[e] If imaging is not available, score these items as 0.

[f] Hyperechoic irregular enhancement over the surface of the hyaline cartilage that is independent of the insonation angle of the ultrasound beam (note: false-positive double-contour sign [artifact] may appear at the cartilage surface but should disappear with a change in the insonation angle of the probe).

[g] Presence of color-coded urate at articular or periarticular sites. Images should be acquired using a dual-energy computed tomography (DECT) scanner, with data acquired at 80 kV and 140 kV and analyzed using gout-specific software with a 2-material decomposition algorithm that color-codes urate. A positive scan is defined as the presence of color-coded urate at articular or periarticular sites. Nailbed, submillimeter, skin, motion, beam hardening, and vascular artifacts should not be interpreted as DECT evidence of urate deposition.

[h] Erosion is defined as a cortical break with sclerotic margin and overhanging edge, excluding distal interphalangeal joints and gull-wing appearance.

RISK FACTORS

The risk factors for drug-induced hyperuricemia and gout (**Table 51-6**) are identical to those for patients with nondrug causes. Male sex increases risk, and gout is 7 times more likely to develop in men than in women. High baseline serum uric acid concentrations increase the risk. Healthy men with serum uric acid concentrations of ≥9 mg/dL are 10 times more likely to have gout than those with concentrations 7–8.9 mg/dL and 50 times more likely than those with concentrations <7. The risk in patients with uric acid concentrations >9 mg/dL is roughly 5% annually. Other factors known to increase risk are a history of hypertension, diet, and obesity.[60,63,87,88] Diets rich in beef, pork, lamb, or seafood, which contain high amounts of purines, can contribute to hyperuricemic states.[89] Conversely, consumption of large amounts of low-fat dairy products is associated with a decreased risk of the development of hyperuricemia and gout.[89] Patients who have a combination of the aforementioned risk factors are at an especially increased risk for drug-induced hyperuricemia and gout.[1] Genetic variations have been explored as causative factors of hyperuricemia and gout, but the clinical relevance of these variations has yet to be determined.[90]

Table 51-6 Risk Factors for Drug-Induced Gout and Hyperuricemia[1]

- Alcohol consumption
- Decreased renal function
- Dehydration
- Elevated baseline serum uric acid concentration
- History of hypertension
- Hyperparathyroidism
- Ketoacidosis or lactic acidosis
- Lead nephropathy
- Lymphoproliferative and myeloproliferative disorders
- Obesity
- Psoriasis
- Sex (male >female)

MORBIDITY AND MORTALITY

Gout as the primary cause of death is extremely rare.[91] As compared to men without gout, an increased risk of all-cause mortality and cardiovascular disease mortality has been found in men with gout.[92] Although acute gout can be severe and lead to clinic or emergency department visits, the condition is generally self-limiting and resolves rapidly with appropriate treatment.

Gout accounted for about 2.3 million ambulatory care visits annually from 2001 through 2005 and was approximately 1.5% of the 1.17 million nonfederal, short-stay hospitalizations in 2007.[93] The estimated medical expenditures attributable to gout were $2,805 per person or $7.7 billion overall.[94]

PREVENTION

Approaches to help prevent drug-induced gout and hyperuricemia are listed in **Table 51-7**. Overall, healthy diets rich in vegetables and low-fat or nonfat dairy products have been associated with a reduced risk of gout.[95] Routine monitoring of serum uric acid concentrations is not currently recommended, as it is not thought to be helpful in predicting risk of gout in an individual patient, and evidence of adverse consequences associated with asymptomatic hyperuricemia is limited at this time. Many patients, even those with hyperuricemia, will not develop gout when given drugs with the potential to precipitate attacks. In most cases, the benefits of drug therapy outweigh the risks associated with an acute gout attack, particularly when one considers the ability to successfully treat the patient should an attack occur and the self-limiting nature of the disease.

Table 51-7 Approaches to Help Prevent Drug-Induced Gout and Hyperuricemia

Ethanol

- Reduced consumption of beer, in particular, but also wine and spirits

Nicotinic acid

- Use another class of lipid-lowering drugs when appropriate according to primary lipid target

Diuretics

- Hydrochlorothiazide doses <50 mg daily and chlorthalidone doses <25 mg daily when clinically appropriate, possibly in combination with other antihypertensives[40]; losartan and calcium channel blockers have shown some benefit in reducing diuretic-induced hyperuricemia[28,39,43-49]

Cytotoxic agents

- Pretreat with hydration, urine alkalinization, and allopurinol or urate[13]
- Allopurinol, febuxostat, and uricosuric agents

- Slowly titrate dose upward following initiation of therapy; encourage strict compliance and avoid unwarranted interruptions in therapy[53]

Patients receiving drugs with the potential to cause gout should be monitored for symptoms that might suggest the onset of disease. From a practical standpoint, however, the severity of pain associated with an attack is such that most patients readily volunteer that information or present for care when an attack occurs.

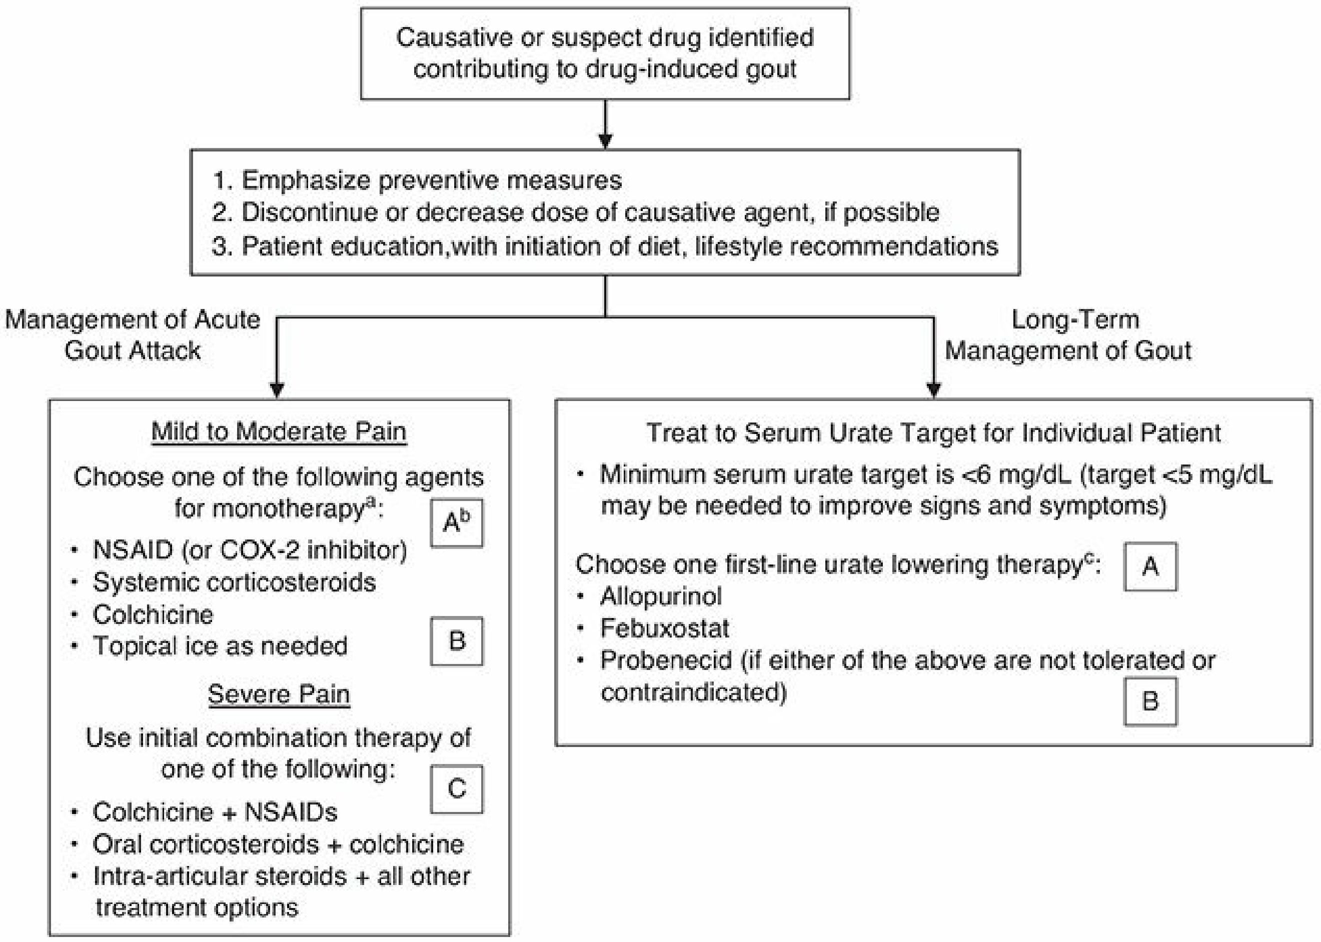
MANAGEMENT

Decisions regarding whether or not to discontinue drugs that may be precipitating gout must be based on an assessment of risk and benefit.[96] When alternative therapy is available, a change to a drug less likely to cause hyperuricemia may be rational, although this strategy may not ensure prevention of future attacks. In some cases, drugs simply unmask patients already predisposed to the disease. These patients are at increased risk for future attacks even without further exposure to the suspect drug. In cases in which a suspect agent is deemed essential to a patient's treatment, prophylactic therapy to help prevent future attacks may be considered.

Hyperuricemia has been associated with renal, cardiovascular, and metabolic risk.[3] However, treatment of asymptomatic hyperuricemia is not recommended, as drug cost and potential toxicity outweigh known therapeutic benefit, although further studies may eventually support the need to treat the disorder to help prevent other complications. Nonpharmacologic and pharmacologic treatment is recommended for individuals who experience signs and symptoms of hyperuricemia and gout.

Limiting the consumption of purine-rich meats (beef, lamb, and pork) and seafood (sardines and shellfish), high fructose corn syrup–sweetened beverages and foods, salty condiments and foods, and alcohol (especially beer) may be of benefit to patients with gout.[3] Consuming low or nonfat dairy products is also encouraged. Dietary changes have been suggested to decrease serum urate by about 10–18%, which may prove beneficial for individuals with hyperuricemia albeit with limited efficacy for those with uric acid levels well above 7 mg/dL.

For individuals with hyperuricemia and at risk for acute attacks of gout, if a decision is made to initiate prophylactic therapy to help alleviate patient discomfort, patients with mild disease may be managed effectively with colchicine or NSAIDs. Similarly, acute breakthrough attacks of gout can generally be treated with NSAIDs or colchicine, particularly when symptoms are recognized early and treated promptly. Patients who experience continued breakthrough attacks despite prophylactic treatment may be candidates for urate-lowering therapy. Allopurinol or febuxostat are recommended first-line treatment agents for individuals who require urate-lowering therapy. The main goals of treatment should be resolution of signs and symptoms and a serum uric acid concentration of 6 mg/dL or less.[3] **Figure 51-1** outlines treatment strategies for gout.



Causative or suspect drug identified contributing to drug-induced gout
1. Emphasize preventive measures
2. Discontinue or decrease dose of causative agent, if possible
3. Patient education,with initiation of diet, lifestyle recommendations
Management of Acute Gout Attack
Long-Term Management of Gout
Mild to Moderate Pain
Choose one of the following agents for monotherapy[a]:
A[b]
• NSAID (or COX-2 inhibitor)
• Systemic corticosteroids
• Colchicine
• Topical ice as needed
B
Severe Pain
Use initial combination therapy of one of the following:
C
• Colchicine + NSAIDs
• Oral corticosteroids + colchicine
• Intra-articular steroids + all other treatment options
Treat to Serum Urate Target for Individual Patient
• Minimum serum urate target is <6 mg/dL (target <5 mg/dL may be needed to improve signs and symptoms)
Choose one first-line urate lowering therapy[c]:
A
• Allopurinol
• Febuxostat
• Probenecid (if either of the above are not tolerated or contraindicated)
B

FIGURE 51-1 Treatment Strategies for Drug-Induced Gout[3,97]

[a] Switch to alternate monotherapy or add-on combination therapy if inadequate response from initial choice. Inadequate response is defined as <20% improvement in pain score within 24 hours OR <50% at 24 hours (evidence grade C).

[b] Evidence Grades for Recommendations: Level A—supported by multiple randomized clinical trials or meta-analyses; Level B—derived from single randomized trial or nonrandomized studies; and Level C—consensus opinion of experts, case studies, or standard-of-care.

[c] Increase dose of urate-lowering therapy if serum urate target is not achieved.
NSAID = nonsteroidal anti-inflammatory drug.

Prophylactic treatment with colchicine or anti-inflammatory drugs is recommended during the initiation of therapy with any of the uricosuric agents to help reduce the likelihood of gout attacks during that time. Colchicine in doses of 0.6 mg 1–2 times daily is recommended as first-line prophylaxis against acute attacks.[96] Alternatively, low-dose NSAIDs such as ibuprofen 200–400 mg once or twice daily or naproxen 250 mg twice daily may also be used.

Xanthine oxidase is important in the metabolism of azathioprine and 6-mercaptopurine, and patients should have azathioprine doses reduced by 75% when allopurinol is administered concomitantly.[98] Even with dose reduction, patients receiving the combination are at increased risk for bone marrow suppression. Azathioprine and cyclosporine are frequently used together in transplant-rejection regimens and, because cyclosporine is associated with gout and hyperuricemia, allopurinol may be prescribed. Caution in determining azathioprine dose is warranted in these situations.[99]

INFORMATION FOR PATIENTS

Patients who receive medications known to increase the risk of hyperuricemia and gout should be warned about the possibility of this disease developing and should be familiar with its common symptoms. Patients should be informed that the risk of gout is quite small and that the condition is self-limiting and relatively easy to manage, particularly when treatment is initiated soon after the onset. Patients receiving prophylactic therapy for gout should understand the importance of continuing therapy as prescribed and should be warned that attacks can be precipitated if medications are stopped and restarted. Patients should also be advised to limit alcohol intake and informed about the benefits of increasing the amount of low-fat dairy products in the diet.[3]

CHAPTER 52

Myopathy

Craig Williams

Over 150 marketed drugs have been associated with myopathy.[1] Although many cases are asymptomatic and self-limiting, the most severe forms can be fatal.[2] The initial diagnosis is usually made clinically, and because appropriate management includes cessation of the causative agent, it is imperative for clinicians to be aware of the drugs commonly associated with myopathy and the presenting signs and symptoms of this drug-induced disease.

Although myopathies are sometimes reported as being painful, they most often present as weakness without pain.[2,3] Patients with weakness may use descriptors such as numbness or fatigue and may describe a general discomfort which is not truly painful. It is, therefore, important to get the patient's accurate history, including a careful description of symptoms. In many cases, elevations in serum creatine kinase (CK) concentration indicate extensive myocyte death, but symptomatic myopathy and weakness may be present without an elevated CK. Because of the varied clinical presentation, the descriptive terminology of myopathy is important. For consistency, the following definitions will be used for this chapter (adapted from a clinical advisory from the National Heart Lung Blood Institute[4]):

- *Myopathy*—a general term referring to any disease of the muscles. Myopathy encompasses all of the following, more specific definitions:
    - *Myalgia*—muscular pain and/or weakness in the absence of elevations of CK.
    - *Myositis*—elevated CK with or without muscular pain or weakness (typically >2 times the upper limit of normal [ULN] which is approximately 200 units/L).
    - *Rhabdomyolysis*—muscular pain and/or weakness with CK elevation (at least >2 times and often >10 times the ULN) and evidence of acute renal disease (myoglobinuria and often, but not necessarily, elevated serum creatinine).

Myopathy associated with substance abuse or toxicity (e.g., ethanol, acetaminophen) or severe hypersensitivity reactions (malignant hyperthermia and toxic epidermal necrolysis) are not addressed in this chapter.

CAUSATIVE AGENTS

Definitive associations with some medications have been established while many others are linked only through case reports (**Table 52-1**).[5-55] Drugs may cause painful or painless myopathies.

Table 52-1 Agents Implicated in Drug-Induced Myopathy

Drug	Incidence	Level of Evidence[a]
Aminocaproic acid[5]	NK	C
Amiodarone[6]	<1%	C
Chloroquine[7,52]	3–5%	C
Clofibrate[8]	5–40%	B
Colchicine[9-11]	NK	B
Corticosteroids (systemic)[12-17,21,b]	1–5%[a]	A
Cyclosporine[18,c]	NK	B
Diuretics[2,19,20]	NK	B
D-penicillamine[21,22]	1%	B
Etretinate[19,23]	NK	C
	NK	C

Ezetimibe[24,d]		
Fibrates[8,25]	2–35%	B
Finasteride[9,26]	NK	C
Hydroxychloroquine[19,27]	1–3%	C
Interferon[28]	2–5%	B
Ipecac[2,19,29,30]	3%	B
Labetolol[31,32]	NK	C
Laxatives[19,27,33]	NK	B
Leuprolide[34]	NK	C
Procainamide[35]	NK	C
Proton-pump inhibitors[36,37,e]	<1%	C
Rifampin[19,20,38]	NK	C
Statins[4,25,39-43,53-55]	1–30%	A
Tenofovir[26,33]	NK	C
Terbinafine[51]	NK	C
Teriparatide[50]	NK	C
Tetracycline[44]	NK	C
Vincristine[19]	NK	B
Zidovudine[45-49]	10–15%	C

NK = not known.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] Incidence much higher with higher doses and with fluorinated steroids.

[c] More common when administered concomitantly with other drugs, especially statins.

[d] More common in patients with previous statin myopathy.

[e] More case reports implicating omeprazole likely reflect greater usage of that agent within the class.

Painful myopathies include necrotizing myopathy, mitochondrial myopathy, polymyositis or dermatomyositis, and neuromyopathies.[23,27,39] Mitochondrial myopathy is clearly associated with zidovudine.[45,46-48] D-penicillamine is most commonly associated with polymyositis, but more recently the proton-pump inhibitors have also been implicated.[27,36,37] Painful neuromyopathies have been reported in association with amiodarone and vincristine and have also been described in patients with electrolyte disturbances caused by drugs such as diuretics, aluminum- or magnesium-containing antacids, isotonic glucose solutions, and licorice.[19,23,26]

Painless myopathies include corticosteroid myopathy, painless neuromyopathies, and some myopathies secondary to drug-induced electrolyte disturbances, particularly hypokalemia and hypermagnesemia.[13,27,31]

EPIDEMIOLOGY

The true incidence of drug-induced myopathy is unknown, but it is likely more common than generally appreciated as many cases are self-limited and unreported.[21,27,31] The incidence varies greatly between causative agents and is based on dose, duration of exposure, risk factors present in the population being treated, and the definition of myopathy applied.

In a 1-year prospective trial reviewing cases of myositis in a large university hospital system, serially measured CK values resulted in an estimated rate of drug-induced myositis of 7.2 per 10,000 inpatients and 9.3 per 10,000 outpatients. Lipid-lowering medications (fibrates and statins) were the causative agents in nearly 60% of the cases, with antiretrovirals accounting for another 14%.[56]

Reports of statin-induced myopathy offer an excellent example of how incidence can vary based on the definition of myopathy used. In the 5-year, 20,536-patient Heart Protection Study (HPS), subjective myalgias were reported in 33% of both the statin- and placebo-treated groups while myositis occurred in only 1.3% of each group and rhabdomyolysis occurred in only 5 patients receiving simvastatin (<0.1%) and 3 patients receiving placebo (<0.1%).[57] Based on these data, it would seem reasonable to expect that case series that include myalgia in the definition of myopathy will report a higher rate of myopathy than those that restrict the definition of myopathy to CK-positive events.

The low incidence of rhabdomyolysis and the relatively high incidence of myalgias reported in the HPS trial are both supported by other research with statins.[40,58] It should be kept in mind, however, that higher-risk patients (e.g., those with chronic renal failure or age >75 years) are often excluded from randomized studies, which can result in an underestimation in the risk of drug-induced myopathies that can occur with more common usage patterns in clinical practice.[43]

Corticosteroid-induced myopathy has been identified as one of the main causes of iatrogenic proximal myopathies and has an estimated prevalence of 3–60%.[12,15,19,26,27] The onset of steroid-induced myopathy is rare within 30 days of initiation.[3] This can be helpful in trying to determine whether the cause of the myopathy is due to the steroid or to the underlying condition for which the steroid is used. The incidence of D-penicillamine–induced myopathy is approximately 1%, and treatment with antimalarial agents has been associated with an incidence of myopathy of 1 per 100 patient-years.[19,59] Myopathy develops in approximately 15% to 20% of patients receiving zidovudine.[23]

MECHANISMS

Drug-induced myopathy can be broadly classified as an endocrine or toxic myopathy which results from disrupted cellular function. Skeletal muscle is a complex, heterogeneous mix of cell types that comprises 40% of adult body mass.[60] Its complexity is due in part to the physiologic complexity of transitioning millions of cells from a resting to a working state and back again within seconds. In the working state, the high energy needs of myocytes are generally met by glycogen, but in the fasting state or states of prolonged work, glycogen depletion leads to the use of free fatty acids as an alternative fuel source.[60,61]

Efficiency is achieved through division of labor with some myocytes (type I) designed to sustain slow, prolonged work and others (type II) designed for quick bursts. Cells that provide prolonged work rely heavily on a constant mitochondrial supply of energy with which some drugs can interfere.[61]

Generating muscle contractions involves the propagation of an action potential. Drugs that directly or indirectly affect electrolyte concentrations can affect the ability of myocytes to initiate or maintain contraction, leading primarily to painless myopathies characterized by weakness. The exact mechanisms by which most drugs cause myopathies are unknown, but some broad categories have been described based on histopathologic and clinical findings (**Table 52-2**).

Table 52-2 Mechanisms of Drug-Induced Myopathy

Drug	Mechanism
PAINFUL NEUROPATHIES	
Aminocaproic acid[5] Clofibrate[8,54,55] Etretinate[19] Ezetimibe[24] Fenofibrate[8,25,54] Gemfibrozil[8,25,54] Statins[25,40,41,43,53,57,58]	Necrotizing: Necrosis of muscle fibers with myophagocytosis and typically marked elevation of CK
Ipecac[2,19] Zidovudine[45-49]	Mitochondrial: Impaired mitochondrial function often secondary to inhibition of mitochondrial DNA polymerase
D-penicillamine[21,22] Proton-pump	Polymyositis/dermatomyositis: Inflammatory reaction; may involve eosinophil infiltration

inhibitors[36,37]	
Amiodarone[6]	Lysosomal: Accumulation in intracellular lysosomes disrupts normal lysosomal function and impairs vacuolar clearance of cell debris; vacuole accumulation causes cell dysfunction
PAINLESS MYOPATHIES	
Corticosteroids[12-15]	Enhanced intracellular protein breakdown and altered calcium homeostasis; CK may or may not be elevated
Chloroquine[30,52,59] Diuretics[2,19] Hydroxychloroquine[19,59] Laxatives[19,33]	Neuromyopathy: Deranged ion transport impairs neuromuscular signaling; may become painful if prolonged Some evidence of impaired glycogen production and storage
Colchicine[9-11]	Antimicrotubular: Binding to intracellular tubulin leads to altered microtubular function resulting in altered peripheral nerve conduction and changes in muscle cell structure

CK = creatine kinase, DNA = deoxyribonucleic acid.

NECROTIZING MYOPATHY

Necrotizing myopathy, also known as metabolic myopathy, is associated with underlying abnormalities in energy production that can ultimately lead to myocyte death. It is most frequently associated with statins and fibrates, although there is some evidence linking nicotinic acid, aminocaproic acid, and high-dose vitamins A and E to this disorder as well.[39,42] The mechanism of statin-induced necrotizing myopathy is unknown. However, it likely involves interference with cellular metabolism either directly by interfering with the production of important intracellular proteins or mitochondrial function or indirectly by reducing the availability of fatty acids as a fuel source to working skeletal muscle.[3,27,62] Other possible mechanisms for statin-induced myopathy include disruption of glycoprotein synthesis in muscle membrane, a decrease in chloride channels in the muscle membrane, increases in intracellular calcium concentration, and decreased cell membrane fluidity.[39,43]

MITOCHONDRIAL MYOPATHY

Zidovudine is one agent that is most commonly associated with mitochondrial myopathy.[27,45,47] A direct toxic effect of the drug on muscle mitochondria is believed to be involved. Drug-induced vascular damage or dysfunction leading to muscle ischemia is also suspected.[20] Dalakas et al.[45] determined that zidovudine causes abnormal mitochondrial function by inhibiting γ-deoxyribonucleic acid (DNA) polymerase, an enzyme found exclusively in the mitochondrial matrix. Inhibition of this enzyme results in interference with the replication of mitochondrial DNA and leads to abnormal accumulation of lipid and glycogen in the muscle cells. The authors found that some subjects improved with the addition of prednisone to their medication regimen, suggesting that an inflammatory process may also be involved.[45]

POLYMYOSITIS AND DERMATOMYOSITIS

Drug-induced polymyositis and dermatomyositis are manifestations of autoimmune microvascular injury most often involving autoantibodies directed at endothelium in connective tissue. It has been classically associated with D-penicillamine, which exerts complex effects on cellular and humoral immune mechanisms, including reducing serum concentrations of Immunoglobulin M rheumatoid factor and depressing T-cell activity. These effects may be desirable for the treatment of rheumatoid arthritis, in which immunoregulatory alterations may be beneficial because of the nature of the disease. However, it is possible that the immunoregulatory disturbances created by D-penicillamine may lead to a loss of tolerance to muscle antigens, resulting in an immune response, manifested by inflammation and subsequently an inflammatory and autoimmune myopathy.[27,29,62] Polymyositis and dermatomyositis may also result from drug-induced necrosis, regeneration, and inflammation of muscle fibers.[31] The incidence of polymyositis and dermatomyositis with newer, more targeted immunotherapies such as infliximab and rituximab is extremely low with a rate in clinical trials that is not different from placebo.[63]

ELECTROLYTE DISTURBANCES

Myopathies may be induced by drugs through indirect mechanisms as may occur with diuretic-induced hypokalemia, hypophosphatemia, or by hypermagnesemia induced by overuse of magnesium-containing antacids.[19,26,27] Hypokalemia may result in reduction of cell membrane excitability, leading to decreased neuromuscular transmission.[29] Hypophosphatemia may cause myopathy via depletion of adenosine triphosphate in muscle cells.[26] Hypermagnesemia may cause myopathy by interfering with neuromuscular transmission through inhibition of the release of acetylcholine.[26]

PAINLESS MYOPATHY

The mechanism by which chloroquine and hydroxychloroquine induce myotoxicity is not definitively known, but may be due to drug accumulation in lysosomes, resulting in decreased lysosomal activity and subsequent cellular accumulation of phospholipids and glycogen.[52,64] Colchicine-induced neuromyopathy is thought to result from microtubule damage, leading to altered peripheral nerve conduction and eventual changes in muscle cell structure that are related to intracellular lysosome movement.[10]

CORTICOSTEROID MYOPATHY

The mechanism of corticosteroid-induced myopathy has been debated, and several potential mechanisms exist. Corticosteroids exert a catabolic effect on muscle and may cause atrophy of the type II muscle fibers.[23,26] Corticosteroids also impair glucose uptake and increase protein catabolism, resulting in muscle atrophy.[13] Reduced protein synthesis associated with long-term exposure to corticosteroids can also play a role in the negative protein balance induced by these drugs.[2,12,16] In addition, corticosteroids may cause mitochondrial injury, leading to muscle necrosis.[23]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The presentation of drug-induced myopathy is varied, and common signs and symptoms are listed in **Table 52-3**. Although necrotizing myopathies more commonly occur early in the course of therapy (<6 months after the start of therapy), the time to onset is variable.[27] Drug-induced myopathies that occur after a long period of uncomplicated drug therapy may be caused by patient-specific factors such as changing renal or hepatic function or the recent addition of an interacting drug. Clinicians should be alert to these types of changes whenever a patient presents with signs and symptoms consistent with myopathy that may be caused by a medication that has been used without difficulty for over a year. Myopathy caused by electrolyte disturbances typically has a rapid onset.[27,29] However, because drug-induced disturbances of serum electrolyte concentrations can have a highly variable time to onset, the temporal relationship between initiation of therapy with these agents (e.g., diuretics) and onset of myopathy is also highly variable.

Table 52-3 Signs and Symptoms of Drug-Induced Myopathy[18,20,22,25,26,28,30,32]

Less severe disease

- Decreased or absent reflexes
- Fatigue
- Muscle pain or tenderness

- Muscle weakness
- Normal creatine kinase (<200 units/L)
- Shortness of breath
- Weight loss

More severe disease

- Decreased urine production
- Discolored urine
- Dysphagia
- Dyspnea
- Elevated serum creatine kinase concentration (>400 units/L)

Identification of a causal relationship between a new myopathy and drug therapy is important, as most drug-induced myopathies are reversible upon discontinuation of the causative agent. Symptomatic relief upon cessation of therapy is also an important aspect of the diagnosis.[65] Although a rechallenge often offers the best chance of a definitive diagnosis, it may or may not be indicated based on the initial severity of the myopathy. Other potential causes of muscle symptoms should always be kept in mind (**Table 52-4**). Changes may be present on electromyography or tissue histology, but these tests are usually performed only in more refractory cases to help with the differential diagnosis.[2]

Table 52-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Myopathy[2,18,32,61,62]

- Cushing syndrome
- Heart failure
- Hypothyroidism
- Infection: treponemal (syphilis), mycobacterial (tuberculosis), viral (cytomegalovirus, human immunodeficiency virus, Epstein–Barr, adenoviruses)
- New neuromuscular condition such as amyotrophic lateral sclerosis, muscular dystrophy, or myasthenia gravis
- New or worsening rheumatologic condition such as polymyalgia rheumatica, arthritis, fibromyalgia, systemic lupus erythematosus, or sarcoidosis
- Simple muscle strain or sprain

Often, patients with drug-induced myopathy present with vague or simple muscle pain, which may evolve to muscle tenderness and/or weakness, typically of the proximal muscles (shoulders, upper arms, thighs, and pelvis).[19] In some cases, CK is elevated and electromyography may reveal myopathic changes.[8] The most severe presentation is rhabdomyolysis in which massive loss of peripheral muscle cells leads to release of intracellular contents. The urine darkens because of myoglobinuria, CK is markedly elevated (often defined as >10 times the ULN, but this is somewhat arbitrary), and urine production may decrease if acute renal failure occurs.

Necrotizing myopathy may present with acute or subacute muscle symptoms.[19] Typically, muscle pain, tenderness, and weakness are present in the proximal limbs, although a more generalized presentation is also possible.[2] Histopathologic examination may reveal mitochondrial changes.[2,27]

As previously discussed, mitochondrial myopathies are most frequently linked to antiretroviral drugs, particularly zidovudine. Complicating the diagnosis of zidovudine-associated myopathy is the natural progression of infection with the human immunodeficiency virus (HIV). Patients infected with HIV often have myopathy as part of the disease process. Zidovudine-induced myopathy may be differentiated from that caused by HIV infection by establishing a temporal relationship between initiation of antiretroviral drug therapy and the onset of symptoms of myopathy and by the resolution of symptoms after discontinuation of therapy.[23] Mitochondrial myopathies are usually painful, with pronounced wasting and tenderness.[19] Muscle biopsy in patients with zidovudine-induced myopathy often reveals abnormal mitochondria of varying size and shape. The mitochondria appear disorganized; necrosis, ragged fibers, and inflammatory infiltrates may be observed on microscopic examination.[23] CK may be normal or moderately elevated.[19]

Like necrotizing myopathy, polymyositis and dermatomyositis may present acutely or subacutely; the presentation may also be insidious. Many nonspecific symptoms may be present including fatigue, weight loss, myalgias, or arthralgias. Muscle involvement is usually, but not always, symmetrical. Proximal muscles are often affected, and patients may report pain in the shoulder, the pelvic girdle, or both.[19] Muscle biopsies in patients with dermatomyositis or polymyositis reveal a mononuclear cell infiltrate that begins in blood vessels and extends into the myofibers.[21] Patients with dermatomyositis also have a rash, which is often edematous, symmetrically involving the periorbital area and upper eyelids.[21] CK may be moderately elevated.[31]

Painful neuromyopathies have been associated with vincristine and amiodarone. Patients with vincristine-induced myopathy typically present with proximal weakness, pain, and atrophy, with absent reflexes.[33] The electromyogram is often normal, and muscle biopsy may show necrosis and regeneration.[31] Amiodarone may cause a peripheral neuromyopathy that is associated with peripheral neuropathy, weakness, and muscle pain. The CK is often high, and electromyography may reveal slowing of nerve conduction velocity. Muscle biopsy demonstrates vacuolar myopathy and no inflammation.[33]

Patients with drug-induced electrolyte disturbances resulting in myopathies may present with muscle fatigue or sudden onset of motor deficit with pain, hypotonia, and decreased or absent reflexes.[19,26] CK may be significantly elevated in some cases.[23] In the case of hypokalemic myopathy, muscle weakness is often generalized, and pain may be present or absent.[29]

Painless myopathies often present insidiously, with muscle weakness in the proximal lower limbs, which may subsequently progress to the upper limbs and trunk.[11,19] Peripheral neuropathy may accompany the weakness of the limbs. Facial muscles may also be affected. CK may be normal or elevated to slightly above normal. Electromyography reveals slowing of nerve conduction.[11,19]

Corticosteroid myopathy may develop after long-term therapy or may occur more acutely.[12,14,33] Most commonly, corticosteroid myopathy presents as an insidious process during long-term therapy and mainly involves the proximal muscle groups, particularly in the lower limbs.[19,26,31,33] Because corticosteroids may be used to treat rheumatologic conditions that may themselves be associated with myopathy, it is important to distinguish drug-induced myopathy from that associated with progression of the disease.

Acute corticosteroid myopathy may occur as the result of therapy with high-dose intravenous corticosteroids administered in an acute care setting. The presence of concomitant therapy with a neuromuscular blocking agent increases the risk of occurrence.[16,27] In this setting, myopathy typically presents acutely, with generalized muscle involvement. Respiratory muscles may be affected and serum CK concentrations may be markedly elevated.[27,62]

In patients with corticosteroid-induced myopathy related to long-term therapy, CK is usually not elevated, but urine creatine excretion is increased.[26,33] Muscle biopsy often reveals nonspecific type II muscle fiber atrophy.[26,33] Reflexes are typically preserved, and electromyography reveals myopathic changes.[31] Phosphate depletion secondary to excessive antacid consumption may result in myopathy in patients with concurrent gastrointestinal disease who are taking corticosteroids.[23] In these settings, it is difficult to determine whether the myopathy is secondary to hypophosphatemia or to corticosteroid therapy.[19,23]

In summary, many drugs have been associated with myalgias, which may be related to one of the myopathic processes discussed previously or to other types of drug-induced rheumatic disorders or hypersensitivity reactions.[19] Patients with drug-induced myalgia present with muscle pain that improves after drug discontinuation.

RISK FACTORS

General risk factors for drug-induced myopathy are listed in **Table 52-5** and typically include higher doses of the causative agent, longer duration of exposure, presence of drug interactions, prolonged and vigorous exercise, and genetic predisposition.

Table 52-5 Risk Factors for the Development of Drug-Induced Myopathy[13,22,25,26,32,51]

- Autoimmune disease (specifically, systemic lupus erythematosus and rheumatoid arthritis)
- Concurrent thyroid disorder
- Duration of therapy (longer duration > shorter duration)
- Genetic predisposition
- Hepatic impairment
- High dose of a potential causative agent
- Hypoalbuminemia
- In corticosteroid-induced myopathy—use of fluorinated versus nonfluorinated corticosteroid
- Kidney disease
- Pharmacodynamic interactions
  - Statins plus nicotinic acid or fibrates or ezetimibe (especially in patients with prior statin myopathy)
- Pharmacokinetic drug interactions
  - Neuromuscular blockers plus corticosteroids
  - Statins plus fibrates
  - Statins plus cytochrome P-450 3A4 inhibitors
- Vigorous or prolonged periods of exercise

Drug interactions leading to myopathy can be pharmacodynamic as well as pharmacokinetic. Examples of pharmacodynamic drug interactions include the neuromuscular blocking agents when given with corticosteroids and fenofibrate when given with statins.[25,27,42] The cellular mechanism of these pharmacodynamic interactions are not clear. Pancuronium possesses a bis-quaternary ammonium corticosteroid structure, which may potentiate glucocorticoid toxicity via a common corticosteroid receptor.[27] Fenofibrate, although relatively devoid of the kinetic interaction with statins that gemfibrozil possesses,reduces circulating triglyceride concentrations and may worsen cellular energy metabolism by further reducing delivery of fatty acids to skeletal muscle in patients taking a statin.[42]

Pharmacokinetic interactions account for part of the increased risk of statin-induced myopathy when administered concomitantly with gemfibrozil or inhibitors of the cytochrome P-450 3A4 (CYP 3A4) isozyme.[8,43] The pharmacokinetic interaction with gemfibrozil appears to involve reduced statin glucuronidation.[41] The prevalence of CK >10 times the ULN associated with the combined administration of statins and fibrates has been reported to be 0.12%.[66] Myopathy associated with the combination of a fibrate and statin is more frequent with gemfibrozil but is reported with all fibrates.[25,40,54,66] Case reports of myopathy occurring during combined therapy with niacin and a statin have also been published.[66] Higher doses of drugs that can cause myopathy, particularly zidovudine, corticosteroids, epsilon aminocaproic acid, and statins, increase the risk of this adverse effect.[14,27,45] Dalakas et al.[45] examined muscle biopsy specimens from 20 patients with documented HIV infections in whom myopathy developed. The majority of these patients had been treated with zidovudine at doses ranging from 800 to 1,200 mg daily for a treatment period of 6–11 months. The authors reported that patients taking higher doses of zidovudine for a longer duration are at greater risk for myopathy.

The risk of corticosteroid-induced myopathy appears to increase in patients receiving the equivalent of prednisone doses >40 mg daily.[14,19,23] Myopathy associated with lower prednisone doses appears to be uncommon.[19] Patients requiring more frequent courses of corticosteroid therapy or continuous corticosteroid therapy are also at greater risk for corticosteroid-induced myopathy as are those in whom corticosteroid use extends beyond 4 weeks.[19,23] Excessive, prolonged use of antacids may be associated with electrolyte disturbances resulting in myopathy.[19,26] Long-term use of colchicine has also been associated with myopathy.[10]

Kidney failure has been identified as a risk factor for myopathies secondary to hypermagnesemia.Magnesium is renally eliminated, and patients with impaired kidney function are at much greater risk for myopathies resulting from therapy with magnesium-containing drugs.[26] Kidney failure has also been noted as a risk factor for myopathy associated with fibrates and colchicine.[19]

GENETICS AND GENOMICS

The clear genetic susceptibility to myopathy from anesthetic-induced malignant hyperthermia helped open up investigation into other areas of genetic risk for drug-induced myopathies.[55,62,67] The contribution of genetics can be either pharmacodynamic or pharmacokinetic, including drug transport as well as metabolism. One area of recent discoveries in this field has been with the statins. As of 2007, at least 12 candidate genes had been identified for statin-induced myopathy.[67] Although work in this area continues, the clinical application of these findings remain unclear. As of 2017, no specific genetic tests are recommended to be performed in patients prior to beginning statin therapy.

In a study of 137 patients who experienced myositis while taking atorvastatin, an allele in the *CYP 3A4* gene was found to be associated with severity of myopathy.[68] In another trial of 110 patients with statin myopathy, 10% were found to harbor abnormal genes for proteins related to cellular energy metabolism, particularly carnitine palmitoyltransferase II.[55] The population frequency for the same genetic polymorphisms in unaffected control patients was 2%.

In 2008, an analysis of the myositis cases in the ongoing 12,000-patient Study of the Effectiveness of Additional Reductions in Cholesterol and Homocysteine

(SEARCH) trial was conducted.[69] Among the 6,031 patients who received an 80-mg daily dose of simvastatin, 98 cases of myositis had occurred after an average follow-up of about 6 years. A genomewide analysis revealed a strong association of myositis with a single nucleotide polymorphism located within the gene that encodes for organic anion-transporting polypeptide (OATP)1B1. The OATP transporter is known to be involved in hepatic uptake of some statins, and polymorphisms affect serum concentrations. Patients homozygous for the less active allele had a 17-fold higher risk of myopathy while receiving 80 mg of simvastatin daily.[69]

The discovery of the importance of OATP1B1 illustrates the role that genetics is likely to play in helping to prevent drug-induced myopathies. Approximately 60% of the myositis cases in SEARCH were attributable to the genetic polymorphism in *OATP1B1*. Although about 30% of the population carries this polymorphism, only about 2% of the population is homozygous for the allele. Avoiding high-dose statins in those patients would prevent about 25% of the observed cases of statin-induced myositis. That may be a reasonable trade-off if alternative therapies can be used or if the reaction that can be avoided is particularly severe. Thus, while genetics is unlikely to offer novel therapies for managing drug-induced myopathies in the near future, it could play a key role in identifying high-risk individuals in whom certain therapies should be avoided. Efforts to make the genetic test for OATP1B1 available commercially are underway.

MORBIDITY AND MORTALITY

Because the precise incidence of drug-induced myopathies is unknown, it is difficult to determine the overall incidence of morbidity and mortality associated with this drug-induced disease. In many patients with myopathy, discomfort and difficulty with the activities of daily living are encountered secondary to muscle weakness. Patients may experience difficulty walking up stairs or difficulty rising from a seated position because of proximal muscle weakness. This has the potential to lead to a significant burden on society in terms of increased healthcare costs because of the more frequent visits to healthcare providers associated with muscle pain or weakness in addition to missed days from work.

Because serious clinical sequelae may develop, it is important to recognize and treat this condition as early as possible. Myopathy may rarely result in myoglobinuria and rhabdomyolysis. These myopathic complications may result in death due to kidney failure.

PREVENTION

Although prevention of drug-induced myopathies is difficult, general preventive measures are listed in **Table 52-6**. When drugs known to cause myopathy cannot be avoided, the best strategy is to use the lowest dose possible, avoid or minimize concomitant risk factors, and monitor carefully for onset of symptoms. In general, combinations of drugs listed in Table 52-1, should be avoided whenever possible, especially in high-risk patients.[19,41,43]

Moderate amounts of exercise and physical activity may help prevent corticosteroid-induced myopathy.[13,70] Physical therapy and exercise may help counteract corticosteroid-induced muscle fiber atrophy. However, extremely vigorous or prolonged periods of exercise may paradoxically increase the risk for drug-induced myopathies.[4] In one small study, "supranutritional" doses of antioxidant vitamins were shown to reduce the risk of zidovudine-related myopathy; however, no large-scale trials have been performed regarding the potential effectiveness of this preventive strategy.[46]

Table 52-6 Approaches to Help Prevent Drug-Induced Myopathy[2,18,22,25,26,30,32,51,59,63,64]

- Avoid combining drugs when each has a risk of myopathy, when possible:
  - Statins and fibrates
  - Statins and cyclosporine
  - Use treatment regimens for the human immunodeficiency virus that avoid zidovudine and protease inhibitor therapy
- Avoid higher-risk drugs in patients with cirrhosis and hypoalbuminemia
- Be aware of drugs that can cause myopathy and that have a significant component of renal clearance; adjust dose or avoid use in patients with chronic kidney disease
- Consider genetic screening when drug-induced myopathy occurs; disorders for which genetic testing is available include the following:
  - Carnitine deficiency states
  - Glycogen metabolism defects
  - Ion channelopathy
  - Lipid storage disease
  - Mitochondrial myopathies
- Consider measuring a baseline CK in patients with multiple risk factors or those receiving multiple medications with a known risk of causing myopathy
- Educate patients regarding signs and symptoms:
  - Discolored urine
  - Symptoms in more than one muscle system
  - Weakness in addition to pain
- Make sure patients know whom to contact in case one or more of the above symptoms occur
- For statins: ensure euthyroid state and monitor periodically during therapy, especially in patients >60 years of age
- Use the lowest effective dose of corticosteroids for the shortest possible time

CK = creatine kinase.

For necrotizing myopathy where a nutritional deficiency may be playing a causative role, data for supplementation are lacking. Perhaps best studied is the possible role for coenzyme Q10 in preventing statin-associated myopathy. Although many studies are small and suffer from design flaws including under-dosing of coenzyme Q10 and poor patient selection, a recent study of patients carefully selected to show clear myopathic symptoms with simvastatin found no benefit from 600 mg of coenzyme Q10 compared to placebo.[71]

It is reasonable to measure baseline CK when therapy with a drug known to cause myopathy is started, and particularly when the patient has risk factors for this drug-induced disease.[4,27] An elevated baseline CK (>200 units/L) that cannot be explained by recent, vigorous exercise or injury should prompt reconsideration of the risk and benefit of starting the medication until the CK is reduced to within a normal range. However, routine monitoring of CK is not recommended because there is no evidence that such monitoring is effective for myopathy prevention. Some patients with drug-induced myopathy present without elevations in CK, and concentrations can become elevated from causes other than a drug-induced effect. Therefore, determination of CK is only routinely recommended once a patient has symptoms.[4,19,23]

MANAGEMENT

Beyond discontinuation of the offending agent, there are few treatment strategies for drug-induced myopathy. Reductions in dose can be effective in cases of mild myopathy without marked elevations in CK. This has been best documented for corticosteroids and statins.[3,17,40] In cases of myopathy with marked elevations of CK, management focuses primarily on supportive care when needed and trying to prevent or minimize the renal complications of rhabdomyolysis.

When a drug-induced myopathy is suspected, evaluation of current and recent past medications is critical. Temporal relationships between drug initiation and the onset of myopathic symptoms should be determined. The potentially causative drug should be discontinued. In the majority of patients with drug-induced disease, symptom resolution occurs, in some cases almost immediately, after drug discontinuation. However, complete resolution or maximal improvement of symptoms may not occur for several weeks after discontinuation of the causative drug.[33] In some cases, particularly in patients with mitochondrial myopathy or polymyositis, a short course of therapy with a corticosteroid such as prednisone may be helpful. Specific recommendations regarding dose and duration of corticosteroid treatment vary; higher doses of prednisone are typically recommended for initial treatment, followed by tapering of the dose.[43] One recommendation for management of drug-induced polymyositis is prednisone 50–100 mg daily for up to 7 days or until acute symptoms resolve, followed by tapering of the dose over a period of months.More rapid tapering may be tolerated, but caution is advised with tapers of <1 month due to risk of polymyositis reactivation. After resolution of the myopathy, it is typically best to avoid future use of the offending agent or to use lower doses if treatment with the drug is absolutely necessary. Changing agents within a class of drugs can often be helpful, but the clinician should be alert for symptom recurrence. In a trial of 45 patients with statin-associated myopathy, 43% tolerated a different agent.[53]

Pascuzzi outlined suggestions for the treatment of patients with HIV infections who present with myopathy.[26] If the patient has been taking high-dose zidovudine for a prolonged period, therapy should be discontinued. This is not difficult in the modern era of HIV therapies where many alternate treatment options now exist. If the myopathic symptoms were due to zidovudine, improvement should be seen over 4–8 weeks. If the patient's symptoms do not improve within this time, a muscle biopsy may be performed; if inflammatory changes are present, temporary treatment with corticosteroids may be helpful. If the patient has myopathy in the absence of therapy with zidovudine, the myopathy is likely related to the disease, and treatment with appropriate antiretroviral therapy may help. Finally, if the patient has acute, fulminant myalgias or weakness, muscle biopsy should be performed to investigate the possibility of an opportunistic infection within the muscle.

The management of corticosteroid-induced myopathy typically requires discontinuation of the causative medication. Following discontinuation, many patients experience complete resolution or significant improvement in symptoms. In others, however, only partial symptom relief may occur. If it is not possible to permanently discontinue corticosteroid therapy following resolution of myopathy without recurrence of the patient's primary disease, treatment may be restarted at a lower dose. Using doses of prednisone <40 mg daily (or equivalent doses of other corticosteroids) may help prevent myopathy recurrence.[3,23]

In patients with myopathy due to drug-induced electrolyte abnormalities, discontinuation of the offending agent usually results in symptom improvement. Occasionally, potassium supplementation may be necessary for the correction of hypokalemia.[23] If drug-induced hypermagnesemia causes myopathy, discontinuation of the causative drug is necessary, and administration of calcium gluconate or, in severe cases (i.e., serum magnesium concentration >14 mEq/L), hemodialysis may be necessary.[26]

In patients who develop symptoms of myopathy while receiving statin therapy, a CK should be determined.[58] If the CK is <5 times the ULN, statin therapy may be continued, and the CK should be determined again 1 week later. However, if the initial CK is >5 times the ULN, statin therapy should be withheld and CK monitored weekly to monthly until values return to the normal range. It should be noted that product labeling for statins recommends discontinuation when CK reaches 10 times the ULN. However, severe reactions can progress when initial elevations are in the range of 3–10 times the ULN, and withholding the drug when CK elevates to 5 times the ULN appears to be a reasonable clinical approach.[4,27]

Regardless of the etiology, once CK is markedly elevated (>10,000 units/L) in the setting of rhabdomyolysis, aggressive hydration is indicated to reduce the risk of permanent renal damage. Although there is no universal protocol, intravenous hydration at a rate of 3–5 mL/kg/hr is reasonable and should be targeted to a rate of urine output of 2–3 mL/kg/hr. Monitoring of urine pH and using sodium bicarbonate to alkalinize urine is poorly supported and is unnecessary. Aggressive hydration can be stopped once serum CK has dropped below 10,000 units/L.

INFORMATION FOR PATIENTS

Although it may not be practical or desirable to warn every patient about the potential for myopathy with every drug listed in Table 52-1, a warning seems appropriate for patients prescribed a drug for which strong evidence of causation exists (i.e., drugs in Table 52-1 with level of evidence A or B). These patients should be counseled to recognize symptoms of muscle pain or weakness, particularly in the proximal muscles, and instructed to contact a healthcare provider if such symptoms occur. Patients should also be warned about the possible significance of darkened urine, especially if accompanied by a reduction in urine output. The patient should be advised to maintain a complete and accurate list of medications and to share this list with providers at each encounter to help minimize the risk of drug interactions that can increase the risk of myopathy. Patients should also be aware that, in some cases, the development of myopathy may be a secondary complication of a specific disease process, and other medical conditions can increase their risk for drug-induced myopathies.

Weight Gain

Amy Heck Sheehan

Weight gain is a complex process involving environmental and genetic factors that ultimately contribute to a metabolic imbalance between caloric intake and energy expenditure. Although weight gain is most commonly associated with lifestyle factors, it also may occur as an unintended response to drug therapy. Drug-induced weight gain increases obesity-related health risks and may compromise patient adherence to drug therapy. Observational studies have reported that a modest weight gain of ≥5 kg in healthy adults is associated with a significant increase in the risk for hypertension, type 2 diabetes, and coronary heart disease.[1-4] For adults who are already overweight or obese, increases in body mass index (BMI) are associated with greater risks of fatal and nonfatal coronary heart disease, fatal and nonfatal stroke, diabetes, and all-cause mortality.[5,6]

CAUSATIVE AGENTS

Drugs that have been reported to cause clinically relevant weight gain—defined as weight gain of ≥5 kg—are listed in **Table 53-1**.[7-275] Drugs listed in this table include only those associated with unintended weight gain. Drugs that are used to promote weight gain are not included.

EPIDEMIOLOGY

According to current guidelines, a BMI (the weight in kilograms divided by the square of the height in meters) ≥25 defines overweight, and obesity is defined as a BMI ≥30.[6] The number of overweight and obese individuals in the United States has increased significantly over the past several decades, and the latest epidemiologic data estimate that approximately 69% of the U.S. adult population is overweight or obese.[276]

The exact incidence of clinically relevant drug-induced weight gain is unknown. Estimating the incidence is complicated because body weight fluctuations are multifactorial and can depend on variables such as lifestyle, habits, genetic predisposition, and concomitant disease states.

Because the majority of drugs associated with clinically relevant weight gain are used in the management of psychiatric disorders, most data regarding the incidence of drug-induced weight gain have been generated from this patient population. Weight loss is a common symptom of many untreated psychiatric disorders, including depression and schizophrenia. Therefore, successful treatment of these disorders with appropriate drug therapy may be associated with weight gain that returns the patient's body weight to baseline. Unfortunately, baseline body weight measurements prior to the development of psychiatric illness are typically not available, making it difficult to assess true drug-induced weight gain.

Table 53-1 Agents Implicated in Drug-Induced Weight Gain[7-275]

Drug	Incidence[a]	Level of Evidence[b]
ANTICONVULSANTS		
Carbamazepine[7-10]	4.7–5.2%[c] (16 wk)[7]	A
Gabapentin[11-14]	2.6% (26 wk)[11]	A
Pregabalin[15-22]	9% (14 wk)[15]; 11.4% (12 wk)[20]	A
Valproic acid[8,22-31]	38%[d] (32 wk)[26]	A
ANTIDEPRESSANTS		
Amitriptyline[32-39]	5.9%[39,e]	A

Bupropion[40]	NK	C
Clomipramine[41,42]	28%[41,e]; 34.8% (2.5 yr)[42]	A
Citalopram[38,42,43]	14.3% (2.5 yr)[42]	A
Desipramine[36,37,44]	NK	A
Doxepin[45,46]	NK	A
Duloxetine[47-51]	8.4–10.8% (34 wk)[48]	A
Escitalopram[47,49,52-55]	10.5–12% (32 wk)[47,53]	A
Fluoxetine[38,42,43,49,56]	6.8% (26–32 wk)[56]; 8.7% (2.5 yr)[42]	A
Fluvoxamine[42,43]	10.7% (2.5 yr)[42]	A
Imipramine[33,57-59]	8.3% (16 wk)[59]; 19.7% (long-term)[59]	A
Maprotiline[60-62]	NK	A
Mirtazapine[32,63-70]	7.5%[32,e]; 49% (8 wk)[32,f]	A
Nortriptyline[33,35,71-73]	NK	A
Paroxetine[38,42,43,48,49,56]	25.5% (26 to 32 wk)[56]; 13.8% (34 wk)[48]; 14.3% (2.5 yr)[42]	A
Phenelzine[74,75]	NK	B
Sertraline[38,42,49,56]	4.2% (26–32 wk)[56]; 4.5% (2.5 yr)[42]	A
Venlafaxine[38,49,67]	NK	B
Vilazodone[76,77]	1% (8 wk)[76]	A
Vortioxitine[78]	NK	B
ANTIPSYCHOTICS (ATYPICAL)		
Aripiprazole[79-102]	5.2–8.1% (4–6 wk)[79]; 5.2–26.3% (4–10 wk)[79,f]	A
Asenapine[103-109]	4.9–5.8% (short-term)[103]; 14.7% (1 yr)[103]	A
Brexpiprazole[110-114]	2–11% (6 wk)[110]; 20–30% (long-term)[11]	A
Cariprazine[115-116]	8–17% (6 wk)[115]	A
Clozapine[117-141]	35% (long-term)[117]	A
Iloperidone[108,142,143]	12–18% (4–6 wk)[142]	A

Lurasidone[144-148]	7% (short-term)[144]	A
Olanzapine[88,91,92,96,98,100,102,108,148,149-170]	22.2% (8 wk)[149]; 64% (long-term)[149]; 40.6% (4 wk)[149,f]; 89% (long-term)[149,f]	A
Paliperidone[102,108,143,171-177]	6–18% (6 wk)[171]; 33% (long-term)[171]	A
Quetiapine[80,102,108,159,178-195]	16% (18 mo)[159]; 8–23% (6–12 wk)[178]; 18.3% (26 wk)[178,f]	A
Risperidone[102,108,155,156,159,163,164,184,186,190,196-209]	14% (18 mo)[159]; 8.7–20.9% (3–8 wk)[196]; 32.6% (3–8 wk)[196,f]	A
Ziprasidone[80,159,210]	7% (18 mo)[16]; 10% (4–6 wk)[210]	A
ANTIPSYCHOTICS (CONVENTIONAL)		
Chlorpromazine[133,211-216]	24.3% (6 wk)[216]	A
Fluphenazine[213,217-219]	NK	A
Haloperidol[162-164,175,202,213,214,218,220,221]	10–22% (4–6 wk)[220-221]; 39–87.5% (1–2 yr)[162,164]	A
Lithium[34,161,222-225]	9.8% (1 yr)[161]	A
Perphenazine[159,211,213,214,226-228]	12% (18 mo)[159]	A
Thioridazine[213,214,229-231]	NK	A
Thiothixene[213,214,232]	NK	A
Trifluoperazine[213,232-233]	NK	A
ANTIRETROVIRAL THERAPY		
Combined antiretroviral therapy[234-240]	NK	B
CHEMOTHERAPY		
Adjuvant chemotherapy for early-stage breast cancer[241-252]	NK	B
HORMONES		
Glucocorticoids[253-258]	NK	A
Insulin[258-265]	NK	A
Medroxyprogesterone[266-275]	NK	A

NK = not known.

[a] Weight gain of >7% of baseline weight as reported in prospective, randomized clinical trials with length of therapy listed in parenthesis.

[b] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[c] Incidence of weight gain >7.5% of baseline weight over 16 weeks of therapy.

[d] Incidence of weight gain ≥10% of baseline weight over 32 weeks of therapy.

[e] Time period of treatment not specified.

[f] Children and adolescents.

Differences in study design and methods also complicate the assessment of drug-induced weight gain. Most studies that have reported data regarding drug-induced weight gain were not specifically designed to assess this outcome. The majority of available information has been generated from adverse event data collected during prospective clinical trials or from retrospective observational studies. These studies include differing criteria for patient inclusion and exclusion, inconsistent definitions of significant weight gain (e.g., >5%, >7%, >10%), variable periods of follow-up, and different methods of reporting weight gain (e.g., kilograms, body mass index) and the extent of weight gain (e.g., mean, median, range, proportion of patients gaining significant weight). Because of these limitations, it is often difficult to compare the incidence and extent of weight gain caused by different medications.

For the purpose of clinical trials, the U.S. Food and Drug Administration defines clinically relevant weight gain as an increase ≥7% of baseline weight. This corresponds to an approximate weight gain of 5 kg in a 70 kg individual. Unfortunately, statistics regarding weight gain are not collected in all clinical trials and therefore data are not available for all drugs. In some cases, clinical trials are not long enough to adequately evaluate a drug's potential to cause weight gain. When available, the incidence of weight gain ≥7% of baseline as reported during prospective, randomized clinical trials is presented in Table 53-1.[7-275]

MECHANISMS

The proposed mechanisms for drug-induced weight gain are specific to each particular class of medication, and for many drugs, the exact cause of weight gain is unknown. **Table 53-2** summarizes the mechanisms of drug-induced weight gain proposed for various drug classes.[20,265,266,277-288]

Table 53-2 Mechanisms of Drug-Induced Weight Gain[20,265-267,278-288]

Drug	Proposed Mechanism
Adjuvant chemotherapy for early-stage breast	NK
Anticonvulsants[20,277,278]	Enhancement of GABA: ↑ appetite and ↓ basal metabolic rate Decreased blood glucose concentrations: ↑ appetite Hyperinsulinemia and hyperleptinemia: ↑ appetite Individual genetic receptor polymorphisms
Antidepressants[279-281]	Blockade of noradrenergic (〈$_2$) receptors: ↑ appetite Blockade of serotonin (5-HT$_{2C}$) receptors: ↑ appetite Blockade of histamine (H$_1$) receptors: ↑ sedation and ↓ physical activity Individual genetic receptor polymorphisms
Antipsychotics[279-283]	Blockade of serotonin (5-HT$_{2C}$) receptors: ↑ appetite Blockade of dopamine (D$_2$) receptors: ↑ appetite Blockade of histamine (H$_1$) receptors: ↑ sedation and ↓ physical activity Blockade of noradrenergic (〈$_1$) receptors: ↑ appetite Blockade of muscarinic (M$_1$) receptors: ↑ appetite Individual genetic receptor polymorphisms
Antiretroviral therapy[285]	Improved health status: ↑ appetite Increases in visceral adipose tissue and trunk fat Impaired glucose homeostasis and dyslipidemia
Insulin[265,286]	Promotes glucose uptake into cells: ↑ glycemic control and ↑ energy storage
Lithium[284]	Blockade of cAMP in renal tubules: ↑ thirst (↑ consumption of high-calorie drinks) Blockade of dopamine (D$_2$) receptors: ↑ appetite Inhibition of thyroid hormone synthesis: ↓ basal metabolic rate Enhancement of GABA: ↑ appetite and ↓ basal metabolic rate
Lithium[284]	Blockade of cAMP in renal tubules: ↑ thirst (↑ consumption of high-calorie drinks) Blockade of dopamine (D$_2$) receptors: ↑ appetite Inhibition of thyroid hormone synthesis: ↓ basal metabolic rate Enhancement of GABA: ↑ appetite and ↓ basal metabolic rate
Steroid hormones[266,287,288]	Hypercortisolemia and hyperinsulinemia: ↑ appetite and ↑ energy storage

5-HT = 5-hydroxytryptamine, cAMP = cyclic adenosine monophosphate, GABA = gamma-aminobutyric acid, NK = not known.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The clinical presentation and extent of weight gain caused by drugs may vary depending on the drug class. The extent of weight gain associated with specific drugs and drug classes is presented in **Table 53-3**. Endocrine and psychiatric disorders as well as environmental and behavioral factors should be assessed in the process of differentiating drug-induced weight gain from weight gain due to other causes. Table 53-4 lists conditions to consider in the differential diagnosis of drug-induced weight gain.

Table 53-3 Extent of Weight Gain Reported with Selected Drugs and Drug Classes

Drug	Extent of Weight Gain Reported in the Literature[a]
ANTICONVULSANTS	
Carbamazepine	7–15 kg over 2 mo[8] >7.5% over 4 mo[11]
Gabapentin	6–15% over 6 mo[13] 5 to >10% over 12 mo[15]
Pregabalin	4 kg over 6 mo[19] 5.2 kg over 24 mo[16]
Valproic acid	5.8 kg over 32 wk[26]; 8–49 kg over 7.1 yr[25]
ANTIDEPRESSANTS	
Amitriptyline	0.9–13.6 kg over 8 wk[36]
Bupropion	10 kg over 1 mo[40]
Citalopram	6.9 kg over 12 mo[43]
Clomipramine	4.9 kg over 2.5 yr[42]
Desipramine	0.9–9.5 kg over 8 wk[36]
Doxepin	2.7 kg over 9–13 wk[45,46]
Duloxetine	0.61 kg over 8 mo[47]
Escitalopram	1.83 kg over 8 mo[47]
Fluoxetine	5.2–7.7 kg over 8–12 mo[43,56]
Fluvoxamine	6.3 kg over 12 mo[43]
Imipramine	2.3 kg/mo of therapy[57]
Maprotiline	4.2 kg over 4 wk[62]
Mirtazapine	2.4–16 kg over 1–5 mo[63-65]
Nortriptyline	1.82 kg over 6 mo[73]
Paroxetine	8.2–14.1 kg over 8–12 mo[43,56]
Phenelzine	>6.8 kg over 4–16 wk[74]
Sertraline	8.6 kg over 8 mo[56]
Vilazodone	1.7 kg over 52 wk[77]
Vortioxitine	0.6 kg over 52 wk[78]
ATYPICAL ANTIPSYCHOTICS	
Aripiprazole	1.7–4.3 kg over 2–3 mo[80,95]
Asenapine	2.63 kg over 7.6 mo[106]
Brexpiprazole	1.5–1.9 kg over 6 wk[114]
Clozapine	4.45 kg over 10 wk[290] 7.5–10.9 kg over 6 mo to 1 yr[120,125,128,130,133,134]
Iloperidone	2.5 kg over 6 wk[143]
Olanzapine	4.15 kg over 10 wk[290] 4.1–12 kg over 6 mo to 1 yr[150,152,153,157,159,160,162-164]
Paliperidone	2.17 kg over 6 mo[175]
Quetiapine	3.4 kg over 1 yr[181]
Risperidone	2.1 kg over 10 wk[290] 2.3–8.9 kg over 1 yr[164,199-202]
Ziprasidone	1.2 kg over 3 mo[290]
CONVENTIONAL ANTIPSYCHOTICS	
Chlorpromazine	2.58 kg over 10 wk[290] 6.5 kg over 1 yr[133]
Haloperidol	0.48 kg over 10 wk[290] 4.2–9.7 kg over 1–2 yr[162,164,202]
Lithium	1.4–11.5 kg over 1–6 yr[161,222-224]
Thioridazine	3.19 kg over 10 wk[290]
ADJUVANT CHEMOTHERAPY	
Adjuvant chemotherapy for early-stage breast cancer	2.3–12.3 kg 1–2 yr after treatment[246,247]
HORMONES	
Depot medroxyprogesterone	4.3–9.4 kg over 1–5 yr[266-275]
Insulin	2.6–8 kg over 2 mo to 1 yr[259,261,262,265]
Prednisone	2.6–13 kg over 1 yr[253-255]

[a] Reported as mean weight gain unless otherwise noted.

ANTICONVULSANTS

Anticonvulsant agents, including carbamazepine, gabapentin, pregabalin, and valproic acid are commonly associated with weight gain in children and adults.[7-31] Anticonvulsant-induced weight gain is generally characterized by an increased appetite and increased calorie consumption.[20] A case series of four patients with epilepsy who were receiving carbamazepine therapy describes weight gain ranging from 7 to 15 kg after 2 months of therapy.[7] A double-blind, randomized study designed to assess efficacy of carbamazepine add-on therapy in patients receiving phenytoin for partial seizures reported weight gain of >7.5% of baseline weight in 4.7% of patients after 16 weeks.[9] A retrospective chart review of 63 patients receiving carbamazepine for bipolar I disorder reported a mean (SD) body weight gain of 3.41 (±8.81) kg after 10 years of therapy.[10]

Table 53-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Weight Gain[4]

Endocrine disorders

- Cushing syndrome
- Growth hormone deficiency
- Hypothyroidism
- Insulinoma
- Leptin deficiency

Environmental and behavioral factors

- Overconsumption of calories
- Sedentary lifestyle
- Smoking cessation

Psychiatric disorders

- Binge eating disorder
- Depression
- Schizophrenia

Gabapentin has been reported to cause dose-dependent increases in weight.[11-14] In a randomized, dose-controlled trial of 275 patients (doses ranging from 600 to 2,400 mg/day), 16 patients (6%) experienced weight gain as an adverse event; 7 (2.6% of the total sample) of these patients experienced a weight gain >7% of baseline weight after 26 weeks of therapy.[11] In a review of 44 patients treated with high-dose gabapentin (mean dose 3,520 mg/day) for intractable seizures, 34% gained 5–10% of baseline weight and 23% gained >10% of baseline weight over a period of at least 12 months.[13] One patient who was receiving 6,000 mg of gabapentin per day discontinued treatment after gaining 27 kg during 1 year of treatment.

Pregabalin has also been reported to cause dose-dependent weight gain.[15-22] During clinical trials assessing the efficacy of pregabalin for treatment of partial seizures, weight gain was reported in 9–20% of patients.[15,16] In a retrospective analysis of 101 patients with epilepsy who were treated with pregabalin add-on therapy for at least 1 year, 26 (25.7%) experienced weight gain greater than 10% of baseline weight.[16] In a 6-month, randomized, controlled trial specifically designed to assess weight gain associated with pregabalin therapy for epilepsy, 41% (25 of 61) of patients experienced a weight gain >5 kg.[17]

Valproic acid and valproate are well recognized as causes of weight gain, with numerous reports in the literature describing significant weight gain in adults and children.[8,22-31] In their review of 16 clinical trials, Jallon and Picard[20] noted that the incidence of weight gain with valproic acid varied from 4% to 71%. The magnitude of weight gain reported in the literature has ranged from 2 to 49 kg during long-term valproate therapy.[22-31] In a prospective, randomized clinical trial specifically designed to assess weight changes associated with valproate as compared with lamotrigine, the average weight gain in patients randomly assigned to the valproate group was 5.8 kg over 32 weeks of treatment, with 38% of patients experiencing a ≥10% increase in weight from baseline.[26]

ANTIDEPRESSANTS

Weight gain induced by tricyclic antidepressant (TCA) medications has been reported to be dose-dependent, treatment-duration-dependent, and typically associated with increased appetite and cravings for sweets and other carbohydrates.[34,37,289] A review of studies evaluating weight gain associated with amitriptyline, nortriptyline, and imipramine reported the average weight increase to be 0.57–1.37 kg per month of therapy.[34] In comparison to other TCAs, amitriptyline has been associated with the largest degree of weight gain.[34-39]

The tetracyclic antidepressants maprotiline and mirtazapine have also been reported to cause significant weight gain in psychiatric patients.[61-70] Mirtazapine increases appetite and has been associated with weight increases ranging from 2.4 kg over 4 weeks of treatment to 16 kg over 5 months of therapy.[62-64] During short-term clinical trials, 7.5% of adult patients and 49% of children receiving mirtazapine experienced a weight gain ≥7% of baseline weight.[32]

Serotonin reuptake inhibitors and mixed serotonergic and noradrenergic antidepressants have been reported to induce small amounts of weight loss during short-term clinical trials.[49] However, the weight loss observed during the early weeks of therapy may be followed by weight gain with long-term treatment.[42,43,47-49,56] Based on available literature, paroxetine appears to be the most likely to induce significant weight gain, followed by sertraline and citalopram.[42,43,49]

Although bupropion is generally viewed as the antidepressant of choice for patients who are overweight or obese because of its propensity to cause weight loss, a recent case report described a woman with major depressive disorder who gained 11 kg over the first month of therapy.[40] This case report may be an anomaly due to the extremely low body weight of the patient at baseline (i.e., 35 kg) and the volume of literature reporting weight loss with bupropion.

Finally, the monoamine oxidase inhibitor (MAOI) phenelzine has been reported to cause clinically significant weight gain, but other drugs within the MAOI class of antidepressants have not been associated with this effect.[74,75]

ANTIPSYCHOTICS

The drug class with the strongest association with significant weight gain is the antipsychotics. A landmark meta-analysis evaluated data regarding weight gain associated with antipsychotics from over 80 clinical trials.[290] Clozapine was associated with the greatest extent of weight gain, with an average gain of 4.45 kg over 10 weeks of treatment in patients receiving standard doses. Olanzapine, risperidone, and ziprasidone were associated with average weight gains of 4.15 kg, 2.10 kg, and 0.04 kg, respectively. Significant mean weight increases of 0.48 kg, 2.58 kg, and 3.19 kg were reported in association with the conventional antipsychotics haloperidol, chlorpromazine, and thioridazine, respectively. In this analysis, placebo treatment was associated with an average weight loss of 0.74 kg over 10 weeks. The investigators used a 10-week treatment period for comparisons because weight measurement data were available at this time point for most patients. Bak et al.[102] conducted a meta-analysis to evaluate longer treatment durations. Longer duration of treatment was associated with greater weight gain for all agents, except ziprasidone and aripiprazole, which appear to have the least should be amount of weight effects.

Average weight gains ranging from 7.5 to 10.9 kg over 6 months to 1 year of therapy have been reported in patients receiving clozapine.[120,125,128,129,133,134] In one study, 21% of outpatients with schizophrenia experienced a weight gain of ≥20% of baseline weight, and 58% of outpatients experienced weight gains of ≥10% of baseline weight during 1 year of clozapine therapy.[125] Additional case reports have documented marked weight gains ranging from 30 to 50 kg associated with clozapine therapy.[119,132,135] In patients receiving olanzapine, average weight gains of 4.1–12 kg have been reported following 6 months to 1 year of treatment.[149,150,152,153,157,159,160,162-164] Of patients receiving long-term therapy with olanzapine during clinical trials (median treatment period, 238 days), 56% experienced a weight gain of ≥7% of baseline weight.[149]

Although conflicting data exist, antipsychotic-induced weight gain does not appear to be dose-related.[291] Weight gain induced by clozapine and olanzapine is associated with increased appetite, carbohydrate craving, and binge eating in some patients.[121,132,292] Based on available information regarding atypical antipsychotic agents, it appears that clozapine and olanzapine are associated with the greatest degree of weight gain.[102,108] Weight gain with olanzapine and clozapine can progress over 6 months to 1 year of therapy before reaching a plateau, with most weight gain occurring during the first 12 weeks.[122,123,153] However, some reports have suggested that clozapine-induced weight gain may persist for up to 3–4 years.[122,131] As compared with other atypical antipsychotics, ziprasidone, aripiprazole, and lurasidone appear to be associated with the smallest degree of weight gain.[102,143,145]

LITHIUM

Weight gain is a common adverse effect of lithium therapy, occurring in up to 65% of patients during long-term treatment.[222-225,284] The average weight gain induced by lithium has been reported to range from 4.5 to 11.5 kg over 1 to 6 years.[222-224] Weight increases of up to 28 kg have been described in the literature.[222] However, an expert panel from The Endocrine Society conducted a meta-analysis of 54 different drugs that did not confirm an association between weight gain and lithium.[258] Women and patients with elevated baseline BMI may be more likely to gain weight with lithium therapy than other patients. Weight gain induced by lithium occurs primarily within the first 2 years of therapy before stabilizing and is characterized by an increase in appetite and thirst, resulting in overconsumption of high-calorie beverages.[222,223,293]

ANTIRETROVIRAL THERAPY

Historically, weight gain associated with antiretroviral therapy has been viewed as highly beneficial and associated with improved health status. In recent years, however, significant advances in the management of human immunodeficiency viral infection have resulted in the availability of highly effective therapies shown to reduce morbidity and mortality.[234] Initiation of combined antiretroviral therapy (cART) has been associated with increases in body weight as well as the risk of cardiovascular disease and diabetes.[234-240] Although the exact cause of weight gain in this patient population has not been confirmed, initiation of cART appears to be associated. Weight gain with cART is associated with increased visceral adipose tissue resulting in impaired glucose homeostasis, dyslipidemia, and an increased risk of cardiovascular disease.[285] In a retrospective review of 681 patients, 20% of patients who initiated cART advanced from a normal or overweight status, to an overweight or obese status following 24 months of therapy.[234] Weight gain in patients who have initiated cART appears to be greatest in the first year of treatment, in women, in those with lower baseline CD4 concentrations, and in those who are receiving protease inhibitors as a component of cART.[236]

CHEMOTHERAPY IN EARLY-STAGE BREAST CANCER

Observational studies conducted in women with early-stage breast cancer have reported significant weight increases in the majority of patients receiving adjuvant chemotherapy.[241-252] Weight gain associated with adjuvant chemotherapy in this patient population has been reported to range from 2.5 to 6.2 kg during the treatment phase, and from 2.3 to 12.3 kg for 1–2 years after treatment.[246,247] Specific drugs reported to be associated with weight gain in this patient population include tamoxifen, prednisone, cyclophosphamide, methotrexate, and fluorouracil.[243,244] In contrast, some studies have reported no significant increases in weight in women who have received adjuvant chemotherapy regimens consisting of cyclophosphamide alone or in combination with paclitaxel.[294] The exact cause of weight gain in patients with early-stage breast cancer is poorly understood but may be related to the underlying disease state, increased calorie consumption, and decreased physical activity.[295,296]

HORMONES

Weight gain is well documented as a consequence of therapy with exogenously administered hormones, including glucocorticoids, insulin, and sex-steroid analogs. In fact, some steroid hormones are specifically used to promote weight gain in certain patient populations.[297-300] Daily oral prednisone therapy has been associated with dose-dependent increases in weight ranging from 2.6 to 13 kg over 1 year of treatment.[253,254] Glucocorticoid-induced weight gain is characterized by central adiposity, which is associated with increased health risks as compared with peripheral obesity.[4,287,288]

Insulin therapy is associated with an increase in body weight in patients diagnosed with both type 1 and type 2 diabetes.[259-265] Weight gain is more common in patients receiving intensive insulin therapy than in those receiving conventional therapy.[259-261,264] Weight gain has been reported to range from 2.6 to 8 kg over 2 months to 1 year of insulin therapy.[259,261,262,265] Although sulfonylurea and thiazolidinedione drugs have been reported to cause increases in weight, particularly when used in combination with insulin, the weight gain associated with these agents alone does not typically exceed 5 kg.[286,301,302]

Conflicting literature exists regarding the significance of weight gain associated with oral contraceptives.[303] Depot medroxyprogesterone has been reported to induce weight gain ranging from 4.3 to 9.4 kg over treatment periods varying in length from 1 to 5 years.[266-275] Adolescents and women with elevated baseline BMI appear to be at increased risk for weight gain associated with hormonal contraceptives.[270,271]

RISK FACTORS

The incidence and extent of drug-induced weight gain differ significantly between patients and across drug classes. Potential risk factors for drug-induced weight gain are listed in **Table 53-5**.

Table 53-5 Risk Factors for Drug-Induced Weight Gain[20,49,222,254,256,268,280,282,284,285,287,291,305-309]

Anticonvulsants[20]

- Dose-dependent (valproic acid, gabapentin)
- Female sex (valproic acid)

Antidepressants[49,279,304]

- Dose-dependent
- Genetic polymorphisms
- Increased treatment duration
- Low baseline BMI
- Weight increases during first week of therapy

Antipsychotic[221,279,281,283,290,305-307]

- Children and adolescents
- Genetic polymorphisms
- Increased treatment duration (clozapine)
- Low baseline BMI
- Positive treatment response[a]
- Treatment with clozapine or olanzapine

Adjuvant chemotherapy for early-stage breast cancer[308]

- Multiagent chemotherapy regimens of long duration
- Premenopausal status

Glucocorticoids[254,255]

- Dose-dependent
- Increased treatment duration

Insulin[286]

- Intensive insulin therapy

Lithium[279,284]

- Elevated baseline BMI
- Female sex

Medroxyprogesterone (depot)[267]

- Adolescents with elevated baseline BMI

BMI = body mass index.

[a]Indicates inconsistent reports in the literature.

MORBIDITY AND MORTALITY

Obesity is a chronic disease that contributes significantly to overall morbidity and mortality.[4,5,309] Epidemiologic data suggest that morbidity and mortality begin to increase with a BMI ≥25.[310] Increased morbidity has also been reported with modest weight increases, even when weight remains within the healthy weight range (BMI, 18–24).[1-4] Obesity is directly linked to the development of hypertension, hyperlipidemia, and type 2 diabetes and is considered an independent risk factor for the development of coronary heart disease.[4] Importantly, obesity may be the second most common factor contributing to preventable death in the United States, second only to cigarette smoking.[311] Obesity and overweight play significant roles in the development of gallbladder disease, degenerative joint disease, sleep apnea, and certain types of cancers. In addition to these health risks, overweight and obesity are associated with a significant psychological burden, potentially leading to depression and other psychological conditions. Therefore, drug-induced weight gain, particularly to the extent that it contributes to overweight or obesity, may be associated with an increased risk of morbidity and mortality.

PREVENTION

Prevention of drug-induced weight gain is achieved primarily through the implementation of counseling strategies that instruct patients and caregivers about behavioral modification, a proper weight-maintenance diet, and routine exercise prior to initiation of the potentially causative agent.[312-315] Studies specifically evaluating the clinical effectiveness of behavioral and dietary interventions to minimize or prevent antipsychotic-induced weight gain have reported small differences in weight changes between patients receiving behavioral dietary interventions and those receiving standard care.[316-318] These interventions appear most effective when they include a combination of cognitive behavioral therapy, reduced caloric consumption, and increased physical activity; when they are implemented at the time of initiation of antipsychotic therapy; and when patients are able to adhere to the therapy for long-term.[316-318] Small studies have also evaluated the efficacy of drug treatment for the prevention of antipsychotic-induced weight gain.[319-327] In general, these studies have reported only modest results. No significant differences in degree of weight gain were reported in association with the concomitant use of drugs such as fluoxetine, nizatidine, and famotidine in patients receiving olanzapine therapy.[319-322] However, evidence suggests that the addition of metformin, topiramate, or zonisamide may reduce weight gain or promote weight loss in patients receiving psychiatric medications.[323-325] Additional studies are needed to define the role of pharmacotherapy for the prevention of drug-induced weight gain. At present, behavioral and dietary interventions are the mainstay for prevention.

For antipsychotic medications, a joint consensus statement issued by the American Diabetes Association, the American Psychiatric Association, the American Association of Clinical Endocrinologists, and the North American Association for the Study of Obesity, provides specific recommendations for patient monitoring with regard to weight.[312] The panel recommends collection of baseline personal and family history regarding obesity and measurement of height, weight, and waist circumference to determine whether the patient is currently overweight or obese or at risk to become overweight or obese in the future. Selection of an antipsychotic agent with less likelihood to cause significant weight gain may be preferable for at-risk patients. The patient, family members, and caregivers should also be informed of the potential for significant weight gain and the subsequent increased risk of diabetes and dyslipidemia. Body weight should then be reassessed at 4, 8, and 12 weeks after the initiation of therapy and quarterly thereafter. The panel recommends switching the antipsychotic agent to another medication with less propensity to cause weight gain if the patient gains >5% of baseline weight during any time in therapy. Approaches to help prevent drug-induced weight gain are reviewed in **Table 53-6**.[293,312-315]

Table 53-6 Approaches to Help Prevent Drug-Induced Weight Gain[293,312-315]

- Consider patients’ baseline height, weight, waist circumference, and risk factors for weight gain when selecting drug therapy
- Educate the patient, family, and caregivers regarding diet, physical activity, and behavior modification
- If patient gains >5% of baseline weight, switch to another agent that is less likely to cause weight gain
- Monitor weight regularly and frequently
- Refer patients to weight-management programs or nutritional counseling

MANAGEMENT

The first step in managing clinically relevant drug-induced weight gain is to consider discontinuation of the causative drug and substituting another agent within the same drug class that is associated with less weight gain. Unfortunately, this option may not always be practical or possible. Potential alternatives to consider for agents implicated as the cause of clinically relevant drug-induced weight gain are listed in **Table 53-7**.[326]

If discontinuing the offending drug is not feasible, behavioral modification in combination with a low-calorie diet and increased physical activity has proven effective for some obese patients taking antipsychotic agents.[316,317] A 1-year study of standard nutrition, exercise, and behavioral interventions in patients with schizophrenia who had gained weight while receiving antipsychotic agents reported an average weight loss of 3 kg, while a comparison group of similar schizophrenic patients receiving usual care experienced an average weight increase of 3.2 kg.[327] Current guidelines recommend a low-calorie diet that reduces daily caloric intake by 500–750 kcal and in combination with increased physical activity and behavioral modification.[6] A realistic treatment goal for the above recommendations is a 5–10% reduction in body weight over 6 months of therapy, which correlates to a loss of approximately 1–2 lb per week.[6]

Antiobesity drug therapy is generally recommended as an adjunct to behavioral modification, a low-calorie diet, and increased physical activity when the combination of these three interventions has failed to produce sufficient weight loss in patients with BMI measurements ≥30 or those with BMI ≥27 who have at least one comorbid condition.[6] Few data exist regarding the efficacy of pharmacotherapy for the treatment of drug-induced weight gain. However, case reports and small studies have reported some success associated with use of amantadine, metformin, orlistat, topiramate, and zonisamide in psychiatric patients with drug-induced weight gain.[319,324,325] Studies have also reported that the adjunctive aripiprazole may decrease weight in patients experiencing significant weight gain associated with stable doses of clozapine or olanzapine.[328-330] Although it appears that some patients may benefit from pharmacotherapy when the combination of behavioral modification, low-calorie diet, and increased physical activity has failed to produce sufficient weight loss, further studies are needed to better define the role of pharmacotherapy in the management of drug-induced weight gain.

Table 53-7 Potential Alternatives for Agents Implicated in Drug-Induced Weight Gain[326]

Anticonvulsants

- Lamotrigine
- Levetiracetam

- Phenytoin
- Topiramate
- Zonisamide

Antidepressants

- Bupropion[a]

Antipsychotics

- Aripiprazole
- Lurasidone
- Ziprasidone

Glucocorticoids

- Disease-modifying antirheumatic drugs (DMARDs)
- Nonsteroidal anti-inflammatory drugs (NSAIDs)

Medications for type 2 diabetes

- Amylin analogs[b]
- Glucagon-like peptide-1 (GLP-1) receptor agonists
- Metformin
- Sodium-glucose cotransporter 2 (SGLT-2) inhibitors

Medroxyprogesterone depot

- Oral contraceptives[c]

---

[a] Although most data support weight loss, one case has reported significant weight gain.[40]

[b] Used in combination with insulin.

[c] Conflicting data exist suggesting decreased efficacy in patients with BMI >27 kg/m2.

INFORMATION FOR PATIENTS

Patients who are to receive medications that may cause clinically relevant weight gain should be informed of the potential for this drug-induced disease prior to initiation of therapy. Moreover, patients should be encouraged to begin a weight-maintenance diet plan and exercise routine prior to the initiation of therapy to help minimize potential weight gain. Appropriate education is a critical component in successful weight management. Therefore, patients should be provided with behavior modification information and education related to appropriate dietary choices and lifestyle modification. In addition, patients should be instructed to monitor their weight to detect any changes during drug therapy.

CHAPTER 54

Temperature Dysregulation

Susan M. Wilson and Ian A. Ross

Normal human body temperature ranges from 36.7°C to 37°C measured orally. Axillary temperatures and those measured rectally are 1°C lower and 1°C higher, respectively. Intraindividual body temperature varies throughout the day and over time, and slight variations may also be noted between individuals. The anterior hypothalamus maintains body temperature within a relatively narrow range by sensing core body temperature and adjusting (homeostatic) mechanisms in the autonomic nervous system. Central dopaminergic and serotonergic pathways are also involved in temperature regulation via the autonomic nervous system. A relative decrease in serum dopamine concentrations or alterations in serotonin balance may lead to autonomic impairment and dysregulation in body temperature. Drugs may act as antigens to induce an immune-mediated response, causing the release of endogenous pyrogens such as interleukin-1 and tumor necrosis factor from leukocytes, resulting in a febrile response.

Drug-induced hyperthermia may be divided into five general categories: altered thermoregulatory mechanisms, drug administration–related fever, fevers relating to the pharmacologic action of the drug, idiosyncratic reactions, and hypersensitivity reactions.[1]

A drug may alter thermoregulation by disrupting central dopamine or serotonin homeostasis, or via peripheral alteration of normal hypothalamic temperature balance, creating an imbalance of increased heat production and reduced heat dissipation.[2] Two such drug-induced dysregulation diseases—neuroleptic malignant syndrome (NMS) and serotonin syndrome—will be discussed in subsequent sections. A rare, but serious, late effect of salicylate toxicity is fever resultant of excess heat production due to an uncoupling of mitochondrial oxidative phosphorylation.[3] Additionally, drugs may affect thermoregulation via modulation of peripheral factors that help maintain normal body temperature, including cutaneous and regional blood flow, hormonal responses, shivering, and sweating.[4-6] Drugs such as anticholinergics, sympathomimetics, prostaglandins, general anesthetics, and thyroid supplements that affect these peripheral factors directly or indirectly will not be discussed in detail in this chapter.

Drug administration–related fever is caused by pyrogens or endotoxins and is often encountered in association with agents derived from microbial products. These pyrogens induce an immune-mediated response causing the release of cytokines such as interleukin-1 and tumor necrosis factor from leukocytes, leading to fever. Examples include fever during amphotericin B and bleomycin infusion. Further, an administration-related response associated with fever may occur in association with drugs given intravenously (phlebitis) or intramuscularly (sterile abscess). Pentazocine and paraldehyde are known to induce such a response when administered intramuscularly.

Fevers relating to the pharmacologic action of drugs are most commonly observed in the treatment of infections or cancer as pyrogen is released from damaged or dying cells. The classic example is the Jarisch–Herxheimer reaction that occurs during the treatment of syphilis. Patients taking clozapine may experience fever potentially due to the immunomodulating effects of increased concentrations of interleukin-6 and tumor necrosis factor.[7,8]

Malignant hyperthermia is a specific idiosyncratic reaction that results in the development of severe fever and muscle damage in susceptible individuals receiving causative drugs. Approximately 5–8% of patients treated with the antiretroviral drug abacavir experience a hypersensitivity reaction characterized by fever, rash, malaise, gastrointestinal, and respiratory symptoms that has been linked to the major histocompatibility complex allele HLA-B*5701. Reactions can be severe enough that screening prior to therapy initiation is required for safe use.[9,10]

Finally, the most common cause of drug-induced hyperthermia is a hypersensitivity reaction. The reaction is mediated through immunologic mechanisms and caused by drugs or their metabolites, most commonly antibiotics.[1]

Conditions to consider in the differential diagnosis of the drug-induced hyperthermia include primary central nervous system disorders (infection, tumors, ischemic or hemorrhagic stroke, trauma, seizures), systemic diseases (infections, cancer, metabolic conditions, endocrinopathies, autoimmune disorders), and toxins (carbon monoxide, phenols, strychnine, tetanus). Drug reaction with eosinophilia and systemic symptoms (DRESS), discussed in Chapter 6: Drug Allergy and Cutaneous Diseases, is another condition in which hyperthermia is often observed. A comparison of the signs and symptoms of the various drug-induced hyperthermic conditions is presented in **Table 54-1**.

Although antipyretics are effective in the treatment of hyperthermia due to drug fever and serum sickness-like reaction, careful temperature monitoring during their use is very important. The mechanism of fever in these cases is a hypothalamus-mediated increase in the body's core temperature. Antipyretics are not effective for the treatment of hyperthermia secondary to NMS, serotonin syndrome, or malignant hyperthermia because the hyperthermia represents an alteration in thermoregulatory balance and hypermetabolism and not a fever.

Drug-induced hypothermia is much less common than hyperthermia and is associated more commonly with illicit drugs rather than with prescription or nonprescription medications. Agents with agonist activity at the gamma-aminobutyric acid (GABA) receptor, such as gamma-hydroxybutyrate (GHB), are often associated with hypothermic effects. GABA is a primary inhibitory central neurotransmitter. GABA, dopamine, serotonin, and opioid peptides are mediators in temperature regulation; the primary effect of GABA is to decrease temperature.

HYPERTHERMIA DUE TO DRUG FEVER

A diagnosis of "drug fever" is generally established when there is a febrile response to a medication, no other cause of the fever may be elucidated, and the fever resolves upon discontinuation of the suspect agent.[1,11] Drug fever tends to be a diagnosis of exclusion following a review of a patient's drug therapy, clinical presentation characteristics, and laboratory values. An early presumptive diagnosis of drug fever and initiation of treatment may reduce unnecessary further evaluation and patient discomfort.

CAUSATIVE AGENTS

Although any drug has the potential to cause drug fever, certain medications should be considered with a higher level of suspicion. Drugs that have been reported to cause drug fever are listed in **Table 54-2**.[12-133] Anticonvulsants, certain antihypertensive drugs, antiarrhythmic agents, and antibiotics are the drugs most commonly associated with drug fever. Antibiotics account for approximately one third of cases.[134] Of the antibiotics, penicillins and cephalosporins are most often implicated. Antibiotics that are rarely or have never been reported to cause drug fever include chloramphenicol, clindamycin, and aminoglycosides.[1,19]

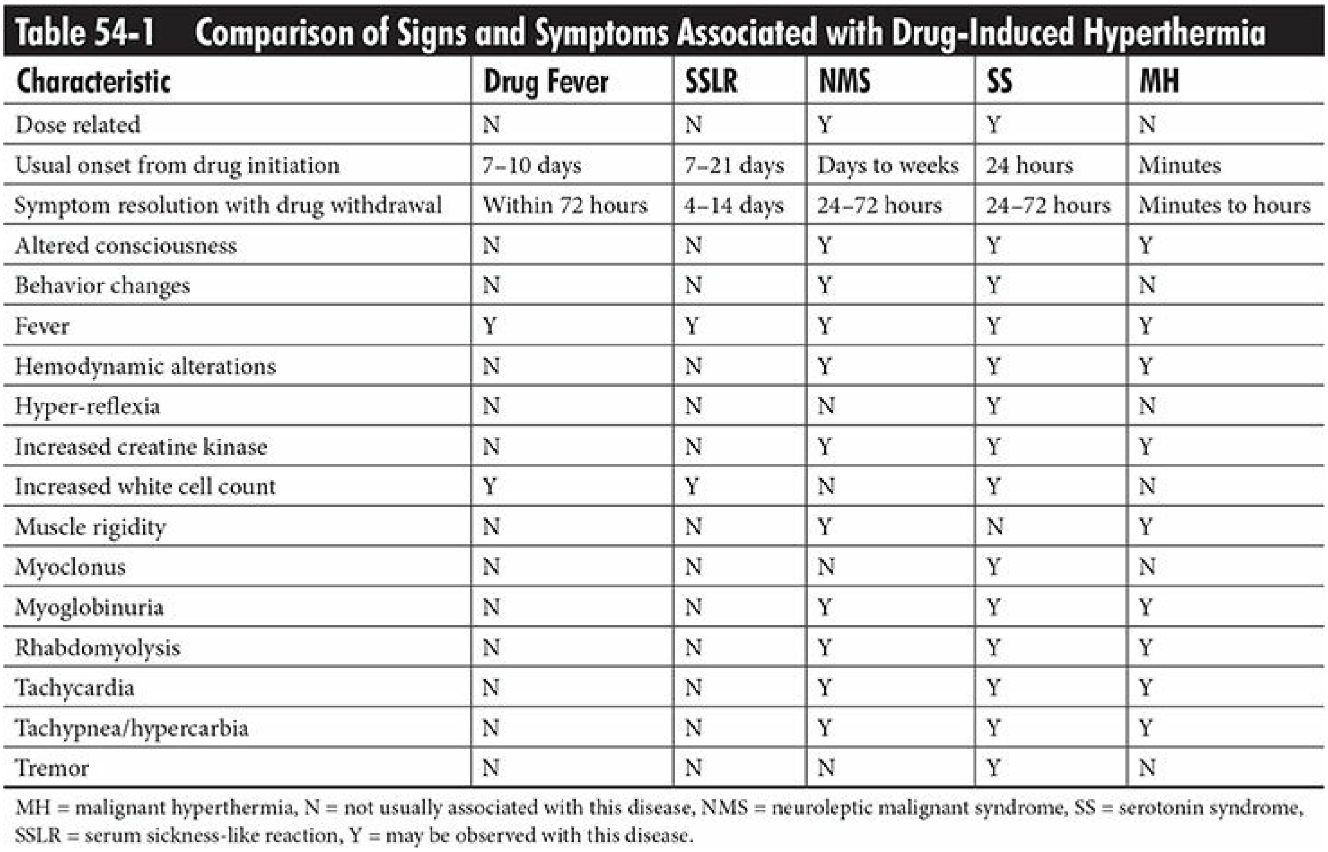

Table 54-1 Comparison of Signs and Symptoms Associated with Drug-Induced Hyperthermia

Characteristic	Drug Fever	SSLR	NMS	SS	MH
Dose related	N	N	Y	Y	N
Usual onset from drug initiation	7–10 days	7–21 days	Days to weeks	24 hours	Minutes
Symptom resolution with drug withdrawal	Within 72 hours	4–14 days	24–72 hours	24–72 hours	Minutes to hours
Altered consciousness	N	N	Y	Y	Y
Behavior changes	N	N	Y	Y	N
Fever	Y	Y	Y	Y	Y
Hemodynamic alterations	N	N	Y	Y	Y
Hyper-reflexia	N	N	N	Y	N
Increased creatine kinase	N	N	Y	Y	Y
Increased white cell count	Y	Y	N	Y	N
Muscle rigidity	N	N	Y	N	Y
Myoclonus	N	N	N	Y	N
Myoglobinuria	N	N	Y	Y	Y
Rhabdomyolysis	N	N	Y	Y	Y
Tachycardia	N	N	Y	Y	Y
Tachypnea/hypercarbia	N	N	Y	Y	Y
Tremor	N	N	N	Y	N

MH = malignant hyperthermia, N = not usually associated with this disease, NMS = neuroleptic malignant syndrome, SS = serotonin syndrome, SSLR = serum sickness-like reaction, Y = may be observed with this disease.

EPIDEMIOLOGY

The true incidence of drug fever is unknown because of underreporting and misdiagnosis. It has been estimated that a drug is the cause of fever in approximately 5–15% of hospitalized patients.[135-137] The incidence is even higher in patients receiving antimicrobials other than antibiotics, such as antiviral agents, and in patients receiving other classes of medications, particularly anticonvulsant and cardiovascular drugs.[16] It has been postulated that the incidence of drug fever is higher in older patients and in female patients; however, this has not been substantiated.[16,135] It has been demonstrated that drug fever due to antibiotics is more likely to occur in younger patients.[19]

MECHANISMS

Drug fever has been hypothesized to be a type III hypersensitivity immune response reaction, based on the time course of the onset of symptoms, the clinical presentation, which may include eosinophilia, and its usual recurrence with rechallenge.[1,19,136,138,139] Drugs or their metabolites may be directly antigenic or act as haptens and combine with endogenous proteins, which become antigens. The immune response may include release of immune mediators and cause the release of pyrogens, thereby inducing fever.

Table 54-2 Agents Implicated in Drug Fever[4]

Drug	Incidence	Level of Evidence[a]

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

Table 54-3 Signs and Symptoms of Drug Fever

- More common
  - Fever
  - Headache
  - Leukocytosis
  - Myalgias
  - Relative sense of well-being
- Less common
  - Elevated erythrocyte sedimentation rate
  - Elevated liver function tests (aspartate aminotransferase, alanine aminotransferase) and alkaline phosphatase
  - Eosinophilia
  - Maculopapular rash
  - Relative bradycardia
  - Thrombocytopenia

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Signs and symptoms of drug fever are presented in **Table 54-3**. The onset of fever is generally 7–10 days from the time of initiation of therapy with the culprit drug. The time of onset may vary by drug class, with the shortest time interval observed with antineoplastic agents (mean of 6 days) and antimicrobials (mean of 7.8 days) and a much longer time interval observed with central nervous system agents (mean of 18.5 days) and cardiac drugs (mean of 44.7 days).[16] Because of this variability, assessment of the temporal relationship between drug initiation and fever onset does not generally aid in the diagnosis. Patients who have been previously sensitized have symptoms much more quickly, usually within hours of reintroduction of the offending drug.

The pattern of fever varies as well and may present as continuous, remittent, intermittent, or hectic.[1,16,17,19,135] Hectic fever is variable or fluctuating; the use of antipyretics or other cooling measures may contribute to this pattern. Chills and rigors may occasionally accompany fever, mimicking the symptoms of sepsis, thereby complicating the diagnosis. Patients may experience a low maximum temperature (T_{max}), or it may be as high as 43°C.[7] No strong association has been made between T_{max} and any patient characteristics, except an inverse relationship between T_{max} and age.[7] Higher temperatures have been observed in patients taking antineoplastic agents; however, this may have been due to the underlying disease.

Cutaneous manifestations are observed in 18–29% of patients during or following drug fever.[1,16,19] After discontinuation of the offending agent, a maculopapular rash can occur that may have an urticarial component with or without petechiae.[16,19,36,58,101,137,140]

Although heart rate typically increases with fever, with drug fever heart rate may not increase to the extent expected relative to the temperature elevation. This "relative bradycardia" in patients without another explanation (e.g., those taking β-blockers or with second- or third-degree heart block) has been used as evidence favoring the diagnosis of drug fever, particularly in patients for whom infection or sepsis is being ruled out.[135,136] Although some patients may experience headache or myalgias, another common observation in patients with drug fever is the sense of well-being relative to the degree of hyperthermia; often patients feel well and are not aware of the fever.[16]

Laboratory abnormalities that may occur with drug fever include leukocytosis, thrombocytopenia, eosinophilia, and markedly elevated erythrocyte sedimentation rate and serum aspartate aminotransferase, alanine aminotransferase, and alkaline phosphatase concentrations.[16,19,36,58,88,101,128,141]

Differential diagnosis of drug fever is difficult because of the inconsistent and nonspecific signs and symptoms described above. Patients often undergo an extensive evaluation and treatment for infection, including blood cultures, radiologic studies, antibiotics, and antipyretic therapy. Multiple studies highlight the cost of diagnostic exclusion and a late diagnosis of drug fever, citing an average of five blood cultures per patient and 2.85 radiological examinations, with an attributed length-of-stay increase of 5.5–8.7 days and an average cost of $9,022 per patient.[140,142] A reasonable effort should be made to rule out other causes (**Table 54-4**). However, depending on the severity of illness, a trial of discontinuing potential fever-inducing medications may be considered.

Table 54-4 Conditions to Consider in the Differential Diagnosis of Drug Fever

- Drug withdrawal (alcohol, benzodiazepines, levodopa)
- Endocrine disorders
- Heat stroke
- Hematologic or solid organ malignancy
- Infection
- Sepsis

RISK FACTORS

Risk factors for the development of drug fever have not been fully elucidated. Patients with a prior drug allergy and those with a history of atopic disease have not been shown to be more susceptible to drug fever.[16] A higher incidence of drug fever has been noted in patients with active HIV infection as well as those with cystic fibrosis. This increased incidence may be due in part to increased use of antibiotics and antiretrovirals in these patient populations.[143-145] Patients with glucose-6-phosphate dehydrogenase deficiency may be at higher risk for drug fever associated with methyldopa because of drug accumulation and higher serum concentrations.[87] Younger patients may be at higher risk for drug fever secondary to antibiotic administration.[19,135]

MORBIDITY AND MORTALITY

The clinical course for patients with drug fever may range from full recovery following very mild illness to significant morbidity and mortality. Drug fever may be the first sign of a hypersensitivity reaction that can prove fatal, even though a direct relationship is rare. In one evaluation of 290 cases of drug fever, 10 patients died.[16] Those who died were more likely to have higher temperatures and an underlying diagnosis of cancer.[16] Most other reviews and cases in the literature have not reported death as a common event associated with drug fever. Continuing the offending agent after a fever appears may put a patient at risk for more serious sequelae, including organ dysfunction, as the syndrome may be expected to worsen. Progression of disease and organ dysfunction is the most probable cause of death due to drug fever.

PREVENTION

The recurrence of drug fever may be prevented by avoiding the offending agent and using an alternative drug if possible. Cross-sensitivity between drugs in the same class is a theoretical concern but has not been reported after the reaction has completely resolved. Given the possibility of recurrence, choosing an agent from another class may be warranted if treatment is to continue. However, after discontinuation of the offending agent, a secondary immune reaction may be observed if the patient is taking another immune sensitizing drug.[1] The mechanism by which this occurs is not well understood but is not thought to be mediated via cross-allergenicity, as these drugs are often pharmacologically unrelated.[137] Desensitization protocols should be implemented in patients for whom no other treatment options are possible. Desensitization is usually accomplished by administering very small doses of the drug via the intravenous or oral route. The dose is gradually increased over hours or days until the full therapeutic dose may be safely administered. In addition to general desensitization guidelines, specific desensitization protocols have been published for many drugs that cause drug fever, including acyclovir, allopurinol, aspirin, imipenem–cilastatin, isoniazid, penicillin, rifampin, ticarcillin–clavulanate, trimethoprim–sulfamethoxazole, chlorambucil, and vancomycin.[146-148]

MANAGEMENT

Discontinuation of the suspected causative agent is the primary treatment, as drug-induced fever is unlikely to remit otherwise (**Table 54-5**). The fever generally resolves within 72 hours of discontinuation of the offending drug, and no other treatment may be necessary. Rarely, 4–5 days may be required for resolution of fever if drug or metabolite elimination is prolonged. For patients receiving therapy with multiple medications and for whom the fever-inducing drug is not known, it is advisable to discontinue all non-life-sustaining medications, particularly those of higher suspicion, including all antimicrobial drugs, if possible. Medications may be reintroduced cautiously, one at a time, if necessary after fever abatement. Corticosteroids may be used to help prevent or treat fever and other manifestations of drug fever if continuation or reintroduction of a particular potential culprit drug is necessary. Corticosteroids are also indicated in patients with severe systemic manifestations of drug fever, including vital organ involvement. Corticosteroids should be used judiciously, particularly in patients with concomitant infection or increased risk of infection or in those with pre-existing immunosuppression from disease or other drug therapy. Antipyretics should be avoided to facilitate monitoring of the patient’s response to discontinuation of suspected sensitizing medications and should be reserved for use as a comfort measure, if necessary.

Table 54-5 Management of Drug Fever and Serum Sickness-Like Reaction

- Discontinue suspected agent
- Discontinue all non-life-sustaining therapies
- Antihistamines may be considered for rash-associated pruritus
- Corticosteroids for treatment of severe systemic signs and symptoms

The risks and benefits of rechallenge should be weighed prior to reintroduction of the suspected agent. Although patients have been rechallenged with relatively few serious sequelae, there is a potential for the occurrence of a faster onset, more severe drug fever reaction upon rechallenge.[16]

Following discontinuation of the suspected culprit drug or drugs, patients with presumed drug fever should be monitored for resolution of signs and symptoms, most importantly fever. Resolution should occur within 72 hours (**Table 54-6**). Patients should also be monitored for signs and symptoms of infection just in case the diagnosis of drug fever was incorrect or in case concomitant infection is present.

Table 54-6 Monitoring Parameters for Patients in Whom Drug Fever or Serum Sickness-Like Reaction Develops

- Blood urea nitrogen and serum creatinine concentrations
- Coagulation profile
- Heart rate
- Liver function tests (aspartate aminotransferase, alanine aminotransferase) and alkaline phosphatase
- Platelet count
- Pulse oximetry
- Respiratory rate
- Serum electrolyte concentrations
- Temperature
- White cell count with differential

INFORMATION FOR PATIENTS

General education of patients receiving a new prescription for a medication that may cause drug fever is imperative. This is particularly important for those receiving prescriptions for antibiotics, anticonvulsants, and other drugs associated with a higher incidence of drug fever. Patients should be counseled regarding the approximate time of onset and signs and symptoms to watch for and should be instructed about when to seek medical attention. Onset of fever within hours of initiating drug therapy, particularly with a drug to which the patient has been previously exposed, requires medical evaluation. A fever that is not associated with other symptoms of infection, and one that is temporally related to the initiation of drug therapy, should prompt the patient to contact a healthcare professional.

Clinicians should instruct patients to be aware of a fever and the corresponding time interval expected for each drug class. Patients receiving antibiotics, central nervous system agents, or cardiac drugs should report a fever that presents within 7–10 days, 3 weeks, or 4–6 weeks, respectively, after initiation of therapy. Finally, patients with a history of safe antibiotic use or a prior experience with drug fever should be instructed to keep this information in their health records and to provide this information to prescribers and other healthcare professionals.

Hyperthermia Due to Serum Sickness-Like Reaction

Serum sickness occurs after the administration of heterologous antitoxin serum. When the syndrome is associated with any other antigenic source, it is known as a serum sickness-like reaction (SSLR).[149,150] Drugs are the most common cause of SSLR. Although antibiotics are commonly implicated, SSLR has been reported in association with a wide variety of medications. SSLR may be a form of drug fever, may accompany drug fever, or may be an extension of drug fever.

CAUSATIVE AGENTS

When SSLR was first described, the primary drugs implicated were those containing antigenic (foreign) material such as antitoxins, vaccines, antivenom, and murine monoclonal antibodies.[151-165] The advent of recombinant human-derived biologic agents has minimized cases of antigenic SSLR. Most recent reports of SSLR have been described in association with antibiotics, classically cefaclor. Rare cases of humanized monoclonal antibody-mediated SSLR have been reported. Drugs that have been reported to induce SSLR are listed in **Table 54-7**.[166-233]

EPIDEMIOLOGY

It is difficult to determine the incidence of SSLR, and most available information is related to antibiotic-associated SSLR. It has been estimated that SSLR occurs in approximately 0.2% of drug courses and in 0.5% of pediatric patients receiving multiple courses of antibiotics.[170] Serum sickness accounts for up to 68% of drug-induced reactions reported in association with cefaclor.[189] One review of antibiotic use found five cases of SSLR in 3,553 courses of cefaclor; five cases in 5,597 courses of amoxicillin; one case in 13,487 courses of trimethoprim–sulfamethoxazole; and one case in 2,325 courses of penicillin.[171] The relative risk of SSLR associated with antibiotic therapy was 65.1. The risk of SSLR associated with cefaclor was 14.8 relative to amoxicillin.

MECHANISMS

Like drug fever, SSLR is probably a type III hypersensitivity reaction, although there may also be a complement independent mechanism whereby the fragment crystallizable (Fc) region of an antibody reacts directly with the gamma receptors of leucocytes.[234-236] The parent drug, reactive metabolites, or a combination of the drug and endogenous proteins may form soluble immune complexes or antigens. These circulating soluble immune complexes deposit in tissues, most commonly joints, and activate an inflammatory response causing the release of mediators such as histamine, serotonin, complement, and platelet-activating factor. This leads to tissue injury and the clinical manifestations of serum sickness.

Table 54-7 Agents Implicated in Drug-Induced Serum Sickness-Like Reaction

Drug	Incidence	Level of Evidence[a]
6-mercaptopurine166	NK	C

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

Table 54-8 Signs and Symptoms Associated with Drug-Induced Serum Sickness-Like Reaction

- Arthralgias
- Edema
- Fever
- Increased C-reactive protein
- Increased erythrocyte sedimentation rate
- Increased liver transaminases (aspartate aminotransferase, alanine aminotransferase), lactate dehydrogenase, and alkaline phosphatase
- Increased serum creatinine
- Leukocytosis
- Lymphadenopathy
- Malaise
- Morbilliform or purpuric rash
- Myalgias
- Urticaria

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The onset of SSLR after primary exposure to a causative drug is usually 6–21 days but may be as long as 4–6 weeks.[198,209,237] The onset following secondary exposure is much shorter, usually 1–4 days.[200,201] The reaction may occur even after discontinuation of a causative agent, and diagnosis can be considerably more difficult in this situation.[173,198] Fever, malaise, and lymphadenopathy are the cardinal symptoms of SSLR (**Table 54-8**). Patients may also experience arthralgias, particularly in the major joints, and myalgias, commonly in the hands and feet. Urticaria and morbilliform or purpuric rashes are common.[179,212,228,238] Edema may occur, usually in the hands and feet or the face and neck, and patients may experience headache or blurred vision. Laboratory abnormalities may include leukocytosis with or without a left shift, increases in aspartate aminotransferase, alanine aminotransferase, lactate dehydrogenase, alkaline phosphatase, serum creatinine, erythrocyte sedimentation rate, and C-reactive protein, although these are inconsistent findings. Proper diagnosis requires careful questioning of patients with the suggestive signs and symptoms. Other conditions to consider in the differential diagnosis include febrile illness, reactive or systemic juvenile idiopathic arthritis, systemic lupus erythematosus, or drug-induced hyperthermic conditions (**Table 54-9**). In general, the presence of fever, arthralgias, and lymphadenopathy, although not always present, are useful clues to the diagnosis of drug-induced SSLR.

Table 54-9 Conditions to Consider in the Differential Diagnosis of Drug-Induced Serum Sickness-Like Reaction

- DRESS
- Drug withdrawal (alcohol, benzodiazepines, levodopa)
- Endocrine disorders
- Heat stroke
- Hematologic or solid organ malignancy
- Infection
- Reactive or systemic juvenile idiopathic arthritis
- Systemic lupus erythematosus

DRESS = drug reaction with eosinophilia and systemic symptoms.

RISK FACTORS

Risk factors for the development of SSLR in children prescribed amoxicillin or cefaclor include younger age (<5 years), longer course of antibiotic therapy, and multiple courses of antibiotics.[171] Risk factors in adults for SSLR due to drugs other than antibiotics have not been identified although some reports suggest a greater likelihood of developing SSLR with higher dosages of antitoxins or antivenoms, intermittent heterologous protein exposure (versus continuous exposure), and concomitant hypergammaglobulinemia with monoclonal antibody administration.[165,221,239]

MORBIDITY AND MORTALITY

In general, the course and outcome of drug-induced SSLR are benign. Hospitalization may be required for patients with significant arthralgic involvement due to disability and for supportive therapy.

PREVENTION

An initial event of drug-induced SSLR is unlikely to be effectively prevented. Judicious antibiotic use, particularly in children, is recommended. The use of cefaclor is associated with a higher incidence of occurrence as compared with that due to other antibiotics; however, this is not reason enough to avoid the use of this agent.

For secondary prevention of SSLR, the offending agent should not be administered again. Another drug from the same pharmacologic class may be initiated, with close monitoring and thorough patient education. There are no data demonstrating a risk of cross-reactivity, and there are cases reported in which another drug from the same class was used without sequelae.[179,240] Fluoxetine, as well as rituximab, desensitization has been implemented successfully in patients with a previous SSLR reaction.[201,241]

MANAGEMENT

Discontinuation of the causative drug is the primary treatment (Table 54-5), and typically signs and symptoms of SSLR will begin to abate within 72 hours.[198] In general, drug-induced SSLR resolves 4–14 days after the discontinuation of therapy, although it may take up to 1 month to completely resolve.[212] Medical management may include antihistamines for urticaria and pruritus and in more severe or worsening cases corticosteroids.[174] Steroids have proven very successful in rapidly reversing symptoms, including rash, joint pain, and facial swelling or edema. Corticosteroids may be administered intravenously or orally in a fixed or tapering regimen over 5–14 days.[174,176,179,187,188,194-196,198,204,205,209,217,218,225] In rare cases, in which discontinuation of the offending agent is not possible, plasmapheresis is an option.[232] Monitoring parameters in patients with SSLR include those listed in Table 54-6, in addition to resolution of rash, pruritus, and arthralgias.

INFORMATION FOR PATIENTS

Patient education is similar for drug fever and drug-induced SSLR. Patients should be aware of the potential for drug-induced SSLR, the approximate onset, signs and symptoms, and when to seek additional medical intervention. Worsening fever, lymphadenopathy, and any joint pain or rash should prompt patients to contact a healthcare professional for further instructions. Patients with a previous history of SSLR should keep this information in their health records and provide this information to prescribers and other healthcare professionals to avoid re-exposure.

HYPERTHERMIA DUE TO NEUROLEPTIC MALIGNANT SYNDROME

First described in 1960, NMS is a serious, idiosyncratic reaction to certain medications, primarily neuroleptics, that results in a relative dopamine depletion causing muscle rigidity, hyperthermia, autonomic instability, and altered mental status.[242] Although NMS is an uncommon disorder, the sequelae may be serious, particularly if the condition is unrecognized and left untreated.

CAUSATIVE AGENTS

Hundreds of cases of NMS have been reported in the literature, most secondary to neuroleptic agents, particularly haloperidol.[243-246] Other agents that inhibit dopamine have been implicated, including prochlorperazine, metoclopramide, lithium, and anticonvulsants.[246-265] Drugs that have been associated with NMS are listed in **Table 54-10**.[243-326] The older, higher-potency antipsychotic agents such as haloperidol and fluphenazine are more likely to induce NMS than the newer, atypical agents such as risperidone and olanzapine, although this may be because there is more experience with and exposure to the older drugs.

Table 54-10 Agents Implicated in Drug-Induced Neuroleptic Malignant Syndrome[197]

Drug	Incidence	Level of Evidence[a]
	NK	C

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies,

retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

EPIDEMIOLOGY

The reported incidence of NMS ranges from 0.02 to 3.23% in patients treated with neuroleptics.[336-343] The true incidence may be higher because of a lack of recognition and underreporting. Retrospective analysis reports the incidence of NMS can be as high as 12%.[344,345] The reported number of NMS cases is decreasing, perhaps because of the availability of newer, lower-potency antipsychotics.[346] NMS occurs approximately twice as commonly in men than in women and has been reported to occur more frequently in young and middle-aged adults, with an average age at occurrence of 40 years, although conflicting evidence exists.[341,343] It should be noted that the apparent higher occurrence in younger male patients may be secondary to a higher incidence of schizophrenia in this population and subsequent higher use of neuroleptics.[347] Patients with pre-existing psychomotor agitation and mental retardation are significantly more likely to develop NMS.[348,349]

MECHANISMS

NMS is a dose-related idiosyncratic reaction that is a result of a relative depletion of dopamine in the central nervous system. NMS may also involve the serotonergic and cholinergic systems. Inhibition of dopaminergic systems in the central nervous system, namely the anterior hypothalamus, and metabolic changes in peripheral skeletal muscle lead to a sustained muscle contraction, resultant heat production, and inappropriate vasoconstriction, decreasing heat dissipation and leading to hyperthermia. This occurs as a result of drug-induced antagonism of dopamine receptors or transmission blockade but has also been reported after changing antipsychotic medications or with the addition of new medications to a neuroleptic regimen that alter additional neurotransmitters such as serotonin. Typical antipsychotics have a greater specificity to antagonize D_2 dopamine receptors, whereas atypical antipsychotics are believed to be more selective toward D_3 and D_4. One proposed mechanism for the decreased incidence of NMS with atypical agents is their ability to also inhibit 5-hydroxytryptamine receptor 2A.[347] Abrupt discontinuation of anti-Parkinsonian agents such as dopamine precursors carbidopa–levodopa and dopamine agonists amantadine, ropinirole, pramipexole, or bromocriptine can produce a subtype of NMS known as Parkinsonism hyperpyrexia syndrome. In these cases, NMS resolves after reinitiation of therapy with these drugs.[255,350-355]

Table 54-11 Signs and Symptoms Associated with Drug-Induced Neuroleptic Malignant Syndrome

- Autonomic dysfunction
  - Hypertension or fluctuating blood pressure
  - Hyperthermia
  - Tachycardia
  - Tachypnea
- Diaphoresis
- Electrolyte abnormalities
  - Hypocalcemia
  - Hypokalemia
  - Hypomagnesemia
- Increased serum creatine kinase
- Leukocytosis with or without a left shift
- Mental status changes
  - Coma
  - Delirium
  - Obtundation
  - Stupor
- Metabolic acidosis
- Muscle rigidity[a] (lead-pipe rigidity)
- Rhabdomyolysis and myoglobinuria

[a] This classic sign may not always be observed in patients with neuroleptic malignant syndrome caused by atypical antipsychotics.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

NMS usually occurs within hours to months after the initiation of neuroleptic therapy or following a dose increase but may take up to a year or longer to manifest. In most cases, NMS develops within the first 4 weeks of therapy with the offending agent. Classic signs and symptoms of NMS (**Table 54-11**) develop progressively over 1–3 days and include hyperthermia, severe muscle rigidity (described as lead-pipe rigidity), autonomic dysfunction (tachycardia, tachypnea, hypertension or fluctuating blood pressure, diaphoresis), and mental status changes (delirium, stupor, obtundation, coma). There tends to be a particular pattern to the onset of the signs of NMS, which may help in early diagnosis and recognition. In more than 80% of cases, mental status changes and rigidity (or serum creatine kinase [CK] elevations) can be expected to precede autonomic dysfunction and hyperthermia.[351] Other signs that may be observed include increased CK concentrations, leukocytosis with or without a left shift, and electrolyte abnormalities (hypocalcemia, hypokalemia, hypomagnesemia). Increased CK concentrations have been found in over 95% of reported cases and may be demonstrated in patients without the classic muscle rigidity.[322,336,356] Elevated CK may also be a function of repeated intramuscular injections to control agitation as well as combativeness against physical restraints. Rhabdomyolysis and resultant myoglobinuria may develop and, without intervention, may progress to renal failure and metabolic acidosis. Temperature elevation may follow other signs and symptoms, and the absence of hyperthermia should not preclude the consideration of NMS. Temperatures of over 38°C are seen in 87% of patients. Temperatures in excess of 40°C occur with a prevalence of 40%.[357] NMS is often confused with heat stroke because both may cause mental status changes and because neuroleptics are a risk factor for both conditions. In contrast to those with NMS, patients with heat stroke present with hot, dry skin, hypotension, and limb flaccidity. Temperature elevation may not be as pronounced in association with the atypical antipsychotics, particularly risperidone and paliperidone.[309,319,358,359] In addition, NMS induced by atypical antipsychotics may be associated with a longer time to onset and the absence of muscle rigidity.[307,360,361] The presence of CK elevations in these patients may be particularly useful in the diagnosis.[360] The clinical presentation in children differs slightly from adults in that children may exhibit more dystonia and less tremor.[369]

Because NMS has various manifestations, differential diagnosis must include many neurologic, psychiatric, systemic, and drug-induced disorders. Catatonia may be an early sign of NMS and may be confused with the underlying illness, leading the clinician to increase the dose of the neuroleptic, which may worsen the condition. Patients with pre-existing catatonia may be at increased risk for NMS, but there is some speculation that NMS and catatonia are part of the same neurochemical syndrome or that NMS is an exacerbation of catatonia.[362-366] Catatonia is usually treated with neuroleptics, and therefore NMS may be more likely to develop because of continued treatment, rapid dose escalation, or higher usage of parenteral neuroleptics. The initial presentation may be helpful for differentiating catatonia from NMS: lethal catatonia often begins with extreme psychotic excitement, often over weeks, with more dystonic movements whereas NMS usually begins with muscle rigidity, although there are exceptions. It should be recognized that there is a relationship between the two syndromes, and in patients with catatonia or NMS with catatonic signs or symptoms, consideration should be given to alternative therapy, such as benzodiazepines or electroconvulsive therapy (ECT).

Abrupt withdrawal of certain medications has been described to produce a NMS-like syndrome. As mentioned previously, cessation of dopaminergic agents can produce the Parkinsonism hyperpyrexia syndrome. Reinstitution of therapy is usually sufficient to alleviate symptoms.[355] Another NMS-like picture occurs in patients who abruptly discontinue therapy with baclofen.[331-335] In the majority of these cases, patients were receiving baclofen intrathecally.[331-333] Patients who have used cocaine may also present with symptoms similar to NMS, including agitation, delirium, and hyperthermia, but often without rigidity. It has been theorized that cocaine enhances dopamine reuptake, such that decreasing serum cocaine levels produces a relative decrease in dopamine transmission.[355]

Serotonin syndrome, anticholinergic delirium, sympathomimetic overdose, pheochromocytoma, thyrotoxicosis, status epilepticus, and lithium toxicity are other disorders with signs and symptoms that overlap with NMS (**Table 54-12**). In one review of 28 patients who met criteria for NMS, 22 also met diagnostic criteria for serotonin syndrome.[311] Another review compared signs and symptoms of NMS induced by olanzapine with the 10 "classical" signs and symptoms of serotonin syndrome. Three or more signs and symptoms of serotonin syndrome were identified in 11 of the 17 patients, indicating considerable overlap between these drug-induced diseases.[367,368]

Table 54-12 Conditions to Consider in the Differential Diagnosis of Drug-Induced Neuroleptic Malignant Syndrome

- Status epilepticus
- Anticholinergic toxicity
- Drug withdrawal (alcohol, benzodiazepines, baclofen)
- Endocrine disorders
- Heat stroke
- Hematologic or solid organ malignancy
- Infection
- Lithium toxicity
- Parkinsonism hyperpyrexia syndrome
- Pheochromocytoma
- Sepsis
- Serotonin syndrome
- Thyrotoxicosis

Despite the creation of rating scales and scoring criteria, there are no universally accepted diagnostic criteria for NMS.[347,370,371] Although it is hypothesized that serum analysis of dopamine and serotonin metabolites can aid in differential diagnosis, other reports cite no clear relationship between NMS and serum antipsychotic levels.[372,373] NMS remains a diagnosis of exclusion. Identification of the causative agent aids in the differential diagnosis. Correct diagnosis is essential, as chlorpromazine, a common treatment option for serotonin syndrome, may worsen signs and symptoms in a patient with NMS.

RISK FACTORS

In a case-control study, higher neuroleptic dose, faster dose escalation, more intramuscular neuroleptic injections, and a greater degree of psychomotor agitation were found to be risk factors for NMS (**Table 54-13**).[374] The incidence of NMS in patients with a high degree of psychomotor agitation may be over-reported due to increased likelihood of higher neuroleptic doses, rapid titration, and frequent intramuscular injections. Other reported risk factors for the development of NMS include use of multiple medications that reduce dopamine transmission, dehydration, concomitant infection, lithium use, exhaustion, pre-existing brain disorder (bipolar disease, delirium tremens, postoperative delirium, Alzheimer disease, and mental retardation), and catatonia, although many patients treated with neuroleptics may possess some of these factors.[338-340,347-350,355,362-364,375-379] In addition, there has been one report of NMS in a patient with bilateral subdural hematoma who had been stable on a neuroleptic agent for 10 years.[262] It is clear that the use of drugs with higher potency, at higher doses, administration via the parenteral route, and history of a prior episode increase the risk for the development of NMS.[249,336,337,341,346,362,374,380,381] There have been reports of NMS cases within families, indicating a possible genetic link, although this link has not been established conclusively. Over-expression of a specific dopamine D_2 receptor gene allele is believed to be related to decreased dopamine receptor function and dopaminergic activity. Involvement of the D_2 receptor may also explain why atypical antipsychotics appear to have a lower propensity to cause NMS.[382-385]

Table 54-13 Risk Factors for Drug-Induced Neuroleptic Malignant Syndrome

Drug-related

- Cotreatment with lithium
- Faster dose escalation
- Higher dose
- Intramuscular route
- Multiple dopamine antagonists

Patient-related

- Alzheimer disease
- Bipolar disease
- Catatonia
- Dehydration
- Exhaustion
- Family history
- Mental retardation
- Psychomotor agitation

MORBIDITY AND MORTALITY

If left untreated or mistreated because of misdiagnosis, NMS can result in very serious sequelae, including permanent disability, coma, and death.[386,387] Mortality has been reported to occur in 4–20% of patients as a consequence of NMS and results from progression of the clinical syndrome.[248,336-338,388] The resultant acute renal failure due to ischemia and rhabdomyolysis, respiratory failure, metabolic acidosis, and electrolyte imbalances may be irreversible and fatal. Venous thromboembolism (VTE) is a major risk for patients with NMS. Although the exact incidence is not known, patients are at higher risk for VTE due to a multitude of factors including immobility, hypovolemia, and increased activation of coagulation factors. Pulmonary embolism is the cause of death in 23% of patients.[389] The rate of mortality has declined over time because of prompt recognition, discontinuation of the offending agent, supportive care, and drug therapy management and is now estimated to be about 10%.[255,339,378] Patients with organic brain disease have a mortality as high as 38.5%. Multiple case reports suggest persistent neurologic functional declines following NMS in patients with underlying traumatic brain injury.[390] There is suggestion of reduced mortality with use of atypical compared to typical antipsychotics.[369,412]

PREVENTION

Because NMS is an idiosyncratic reaction, avoidance is difficult. Recommendations for prevention are listed in **Table 54-14**. The lowest possible dose of neuroleptic drugs should be used to control patient behavior. Patients who are receiving high doses of parenteral neuroleptics or who are having the dose adjusted upward should be well hydrated and monitored for signs and symptoms. Patients with a history of NMS should optimally be treated with an alternative agent, such as a newer, atypical antipsychotic, a drug with lower potency, or a lower dose of the same agent, and treatment should not be initiated or reinitiated until at least 2 weeks after signs and symptoms have resolved.[391-393]

Table 54-14 Approaches to Help Prevent Drug-Induced Neuroleptic Malignant Syndrome

- Avoid lithium cotreatment
- Ensure adequate hydration for patients undergoing active dose escalation
- Rechallenge no sooner than 2 weeks after signs and symptoms have resolved
- Titrate dose slowly
- Use atypical neuroleptics
- Use lowest dose of neuroleptic possible

Overall rates of NMS recurrence are 30–50% following reintroduction of dopamine antagonists.[355] One study reported the experience with rechallenge in 15 patients with a prior NMS episode.[391] Ten patients were successfully rechallenged initially; four of five patients who were unsuccessfully rechallenged underwent a second rechallenge, which was successful in two cases. One of the patients who had a failure was rechallenged a third time, and on that occasion therapy with the neuroleptic drug was successfully initiated and maintained. Overall, neuroleptic agents were tolerated in 13 of the 15 patients with a prior history of NMS. The time from the resolution of signs and symptoms to the rechallenge attempt correlated significantly with success. Twelve of 13 rechallenges were successful if the rechallenge was attempted more than 2 weeks after the signs and symptoms of NMS had resolved, whereas six of seven that were attempted in less than 2 weeks were unsuccessful.[391] Similar results have been reported in other cases of attempted rechallenge.[392,393] Neither the specific neuroleptic agent used nor the dose was found to be a significant factor related to successful rechallenge; however, most rechallenges were attempted with lower-potency agents or lower doses of the same drug.[391] Others have noted that the use of lower-potency agents improves the success of rechallenge as well: 47% and 83% of patients had a relapse when given a drug of equal potency, but only 15% and 10% had a relapse when a lower-potency agent was used.[340,394] Administration of an atypical neuroleptic (clozapine) was used successfully in a patient with three prior episodes of NMS associated with haloperidol, lithium, and molindone.[247] There are other reports of successful atypical antipsychotic rechallenge in 16 of 20 patients who had NMS with atypical antipsychotics.[360,395] Eleven of the patients were successfully rechallenged with the same agent without recurrence of symptoms.

In a patient with a history of NMS, adequate hydration should be maintained, the lowest possible dose of neuroleptic should be used, and the dose should be titrated upward slowly. The use of the parenteral route, particularly depot intramuscular injections, should be avoided. Avoidance of concurrent lithium use may also reduce reoccurrence.[355] Electroconvulsive therapy, as opposed to drugs, should be considered in patients requiring management of an acute psychotic episode and a recent NMS diagnosis (especially of less than 2 weeks).

MANAGEMENT

Strategies for NMS management are presented in **Table 54-15**. In some cases, NMS is a self-limiting disease with signs and symptoms resolving as soon as 7–10 days after the causative drug is discontinued. Therapy should be initiated when rigidity, mental status, and autonomic changes are apparent and the temperature is ≥38°C. However, treatment may be initiated if a presumptive diagnosis of NMS is made prior to the onset of hyperthermia in the presence of other progressing signs and symptoms. One review of published cases reported a mortality rate of 9.7% in patients who received drug therapy (dantrolene, bromocriptine, levodopa, amantadine) as compared with 21% in patients who did not receive any specific drug therapy intervention.[396] Use of dopamine agonists has also been shown to reverse symptoms faster than supportive care alone.[347]

Table 54-15 Management of Drug-Induced Neuroleptic Malignant Syndrome

- Discontinue suspected agent
- Cooling measures and other supportive care
  - Cooled intravenous fluids
  - Fluid and electrolyte replacement as needed
  - Ice water nasogastric lavage or bath
  - Surface cooling
- Bromocriptine 2.5 mg orally 3 times daily up to 45 mg daily for up to 10 days after symptoms abate; then taper over 1 week
- Amantadine 100–200 mg orally 2 times daily for up to 10 days after symptoms abate; then taper
- Dantrolene 1–2.5 mg/kg intravenously 4 times daily until symptoms abate, then 1 mg/kg intravenously every 4–6 hours until able to take orally; oral dosage 1–2 mg/kg 4 times daily for 10 days; then taper
- Benzodiazepines
  - Lorazepam 2–4 mg intravenously or orally as needed for control of symptoms
  - Diazepam 5 mg intravenously or orally as needed for control of symptoms
- Electroconvulsive therapy

All medications that cause dopamine-depleting or antagonistic effects should be discontinued, particularly any antipsychotic agents that have been initiated recently, or for which the dose has recently been increased. Supportive measures include fluid, electrolyte, and acid–base management. Rapid cooling measures, including cooled intravenous solutions, surface cooling, ice bath, and ice water gastric lavage should be used for management of significant temperature elevation.[347]

Bromocriptine, amantadine, other dopamine agonists, and dantrolene have been used successfully in NMS management. Bromocriptine is considered the drug of initial choice. Doses of 2.5 mg 3 times daily, titrated to a maximum of 45 mg/day, should be administered orally for 10 days, although a longer duration of treatment may be required.[266,296,342,355,394-400] Treatment with bromocriptine should be continued until signs and symptoms resolve, after which the dose should be tapered gradually over 1 week.[347] Improvement in signs and symptoms is usually observed within 24–72 hours. Potential side effects of bromocriptine include the potential to worsen psychosis and cause significant hypotension and vomiting.[354]

Amantadine is a treatment alternative for NMS. The recommended dose is 100–200 mg orally twice daily and should be continued for 10 days after signs and symptoms are controlled, after which the dose should be tapered to avoid rebound NMS.[252,401-404]

Dantrolene has been used successfully to treat NMS symptoms by relieving muscle rigidity and heat generation via inhibition of calcium release from the endoplasmic reticulum.[261,405-411] Often patients are unable to take oral medications during NMS, necessitating use of the intravenous route. Dantrolene therapy is recommended if the temperature exceeds 40°C, rhabdomyolysis is suspected, cardiorespiratory or renal failure is imminent, and administration of dopamine agonists has not been successful.[339] These patients have severe NMS and are at high risk of serious morbidity or death and require the most rigorous intervention.[375,412] Dantrolene should be administered at a dose of 1–2.5 mg/kg intravenously 4 times daily until signs and symptoms have been adequately controlled or a cumulative dose of 10 mg/kg is reached. [354,413] Maintenance therapy is 1 mg/kg infused every 4–6 hours to prevent reoccurrence. When the patient is able to take oral medications, dantrolene may be administered at a dose of 1–2 mg/kg every 6 hours orally for another 10 days, and then the dose may be tapered. Intravenous dantrolene is a highly alkaline solution and can cause significant phlebitis. Dantrolene therapy is also associated with hepatotoxicity and should be avoided in patients with liver disease.[354,355] Although combination therapy of a dopamine agonist (bromocriptine or amantadine) plus dantrolene has not shown any proven advantage, it may be considered in refractory or extremely severe cases, as this approach offers treatment with drugs with different mechanisms of action.[409-411,414,415]

Although they successfully control some of the signs and symptoms of NMS, anticholinergic agents are not recommended because they inhibit heat dissipation and may worsen hyperthermia.[338,379,414,415] Hyperthermia in NMS is not prostaglandin-mediated so there is no use for antipyretics such as NSAIDs, aspirin, or acetaminophen.[347] If symptoms are severe and unable to be controlled, requiring intubation or paralysis, the use of a nondepolarizing neuromuscular blocker is preferred over a depolarizing agent. Pancuronium with concomitant diazepam administration was reported to be effective for cessation of muscle rigidity in a patient with NMS in whom treatment with anticholinergics failed but who was not treated with dantrolene.[416] Carbidopa–levodopa may also be effective because of its dopamine agonist properties.[410,411,417] Intravenous diazepam may be used to manage involuntary movements, fever, tachycardia, hypertension, muscle rigidity, tremor, and diaphoresis associated with NMS.[418,419] Benzodiazepines may be useful as adjunct therapy for suspected catatonia and for treatment of agitation.[420-422] ECT may be considered for the treatment of NMS refractory to other therapies, although there are no prospective comparative studies.[423-430] One retrospective review of NMS cases demonstrated a mortality rate of 10.3% in patients who underwent ECT, as compared with 21% in patients who received no specific intervention, a difference that did not reach statistical significance.[396] ECT should be considered the therapy of choice in patients with suspected catatonia.

Resolution of mental status changes, muscle rigidity, serum CK concentrations, acid–base abnormalities, and myoglobinuria should be closely monitored. Progression of these signs and symptoms requires more aggressive management. Monitoring parameters for patients with NMS are listed in **Table 54-16**.

Table 54-16 Monitoring Parameters for Patients with Drug-Induced Neuroleptic Malignant Syndrome or Drug-Induced Serotonin Syndrome

- Coagulation profile
- Heart rate
- Mental status
- Muscle rigidity (NMS)
- Myoclonus (SS)
- Pulse oximetry
- Respiratory rate
- Serum creatinine and blood urea nitrogen concentrations
- Serum creatine kinase concentrations (NMS)
- Serum electrolyte concentrations
- Temperature
- Urine myoglobin concentrations
- White cell count with differential

NMS = neuroleptic malignant syndrome, SS = serotonin syndrome.

With appropriate care, symptoms should resolve within 6–10 days of treatment.[354] Signs and symptoms may persist longer and may be more difficult to manage in patients who have received intramuscular (depot) antipsychotic agents, sometimes necessitating continued treatment for 2–3 weeks, although one case of NMS secondary to long-acting risperidone injection resolved in 10 days.[355,375,385] A residual catatonic state has been described in several patients for 1–6 months after resolution of hyperthermic signs and symptoms.[387] Rigidity and mental status changes persisted in these patients for unknown reasons.

INFORMATION FOR PATIENTS

Patient education may be uniquely difficult in the patient population treated with neuroleptic agents. Despite the potential obstacles, patients and caregivers should be alerted to the signs and symptoms of NMS and instructed when to seek medical attention. Patients and caregivers should be instructed to call a healthcare professional or visit a healthcare facility in the event of sudden onset of muscle rigidity, tachycardia, tachypnea, diaphoresis, or mental status changes. It is particularly important to stress to patients that medications should not be discontinued if signs and symptoms develop and to seek medical attention to ensure that a proper diagnosis is achieved.

HYPERTHERMIA DUE TO SEROTONIN SYNDROME

Serotonin syndrome is a potentially serious and occasionally fatal complication of therapy with drugs that cause an increase in serotonergic activity. Serotonergic neurons are associated with behavioral, motor, and thermoregulation.[355] Fever is one common component of the syndrome. With the significant increase in the number of patients treated with selective serotonin (5-hydroxytryptamine [5-HT]) reuptake inhibitors (SSRIs) and nonselective (serotonin-norepinephrine) reuptake inhibitors (SNRIs), it may be expected that the prevalence of this drug-induced disease will continue to increase.

CAUSATIVE AGENTS

Any drug that causes a direct or indirect increase in the effective serotonin concentration in the central nervous system has the potential to induce serotonin syndrome. Drugs that have been reported to cause serotonin syndrome are listed in **Table 54-17**.[431-531] Included are cases in which drugs were used in combination and the specific causative agent could not be conclusively determined. In addition, paroxetine and fluoxetine are inhibitors of the cytochrome P-450 2D6 enzyme and may increase serum concentrations of serotonergic metabolites when used in combination with trazadone and nefazadone; the combination should be used cautiously. Selective and nonselective SSRIs have been implicated in numerous case reports of serotonin syndrome, as have selective and nonselective monoamine oxidase inhibitors (MAOIs) alone and in combination with opioids. Linezolid has nonselective MAOI properties and has been reported to precipitate serotonin syndrome when combined with a serotonergic agent but also when used with a synthetic opioid analgesic without the presence of an SSRI.[469]

EPIDEMIOLOGY

The incidence of serotonin syndrome is not known but may be as high as 14% in cases of SSRI overdose.[532] Serotonin syndrome has also been reported following ingestion of a single therapeutic dose.[486] However, the true incidence may be relatively low, considering the widespread use of medications, alone and in combination, known to disrupt serotonin balance. One retrospective review examined the use of SSRIs and linezolid, a weak inhibitor of MAO, and found that 3% of patients had a high likelihood of having experienced serotonin syndrome without definitive diagnosis.[466] In another retrospective review of the records of 262 hospitalized patients treated with meperidine, 10% were receiving concomitant SSRIs; serotonin syndrome did not develop in any of them.[533] The sample size in this report was small, and the SSRI doses were not discussed. Although there is an increased awareness of the triggering factors for serotonin syndrome, the disease is still not commonly considered in patients presenting with suspicious signs and symptoms. SSRIs are being prescribed with increased frequency; however, there is declining use of MAOIs, resulting in an unknown net effect on the true incidence of this drug-induced disease.

MECHANISMS

Mechanisms by which drugs cause serotonin syndrome are presented in **Table 54-18**. Excessive serotonergic activity in the peripheral and central nervous system is responsible for serotonin syndrome.[534] Fever in serotonin syndrome is due to a combination of neuromuscular effects combined with altered hypothalamic homeostasis.[355] Seven 5-HT receptor subtypes have been identified, and it is believed that 5-HT$_{1A}$ and 5-HT$_{2A}$ are involved specifically with the adverse sequelae encountered with serotonin syndrome.[535,536] Although controversy exists regarding which of these two receptors is most responsible for the syndrome, it is likely that both of these receptor subtypes, and possibly others, are involved in the clinical manifestations of serotonin syndrome. The syndrome generally occurs after initiating therapy with, or increasing the dose of, a drug with one or more of the following actions: (1) inhibition of serotonin metabolism; (2) potentiation of serotonin activity; (3) direct activation of serotonin receptors; (4) inhibition of serotonin uptake; and (5) increase of substrate supply. Substrate supply may be increased through supplementation with over-the-counter products or consumption of foods such as wine or cheese known to have high levels of the serotonin precursor tryptophan.[537] Serotonin syndrome has been associated with single-drug therapy; however, because it is a dose-dependent phenomenon, combinations of drugs in particular are associated with the development of the syndrome. Both a combination of drugs that have a similar effect on serotonin as well as pharmacokinetic drug interactions, resulting in an increase at the serotonin receptor, can lead to excessive serotonergic effects.[472,491] There is much debate as to the potential for the antimigraine "triptan" class of drugs to trigger serotonin syndrome given their ability to act as 5-HT$_{1B}$ and 5-HT$_{1D}$ agonists.[538,539] Serotonin syndrome may also be precipitated by the addition of other drugs that inhibit cytochrome P450 2D6 or 3A4, such as ritonavir, leading to an increased drug concentration in an otherwise stable regimen. In one case, serotonin syndrome occurred in a patient taking a maintenance dose of sertraline after the addition of erythromycin.[493,534] Some drugs inhibit the metabolism of SSRIs while some SSRIs inhibit cytochrome P450 2D6, which metabolizes other drugs with serotonergic effects such as dextromethorphan. In general, opioid analgesics are thought to inhibit the reuptake of serotonin, thereby increasing the risk of serotonin syndrome when combined with agents that have serotonergic activity. There may be other mechanisms involved, however, as serotonin syndrome has been reported with oxycodone and buprenorphine, which do not inhibit the reuptake of serotonin.[477,515] Other neurotransmitters such as *N*-methyl-d-aspartate antagonists or GABA may play a role.[537]

Ziprasidone[530,531]	NK	C
Metoclopramide + venlafaxine[495]	NK	C

MAO = monoamine oxidase, NK = not known, SNRI = serotonin norepinephrine reuptake inhibitor, SSRI = selective serotonin reuptake inhibitor, TCA = tricyclic antidepressant.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials;

Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

Table 54-18 Mechanisms of Drug-Induced Serotonin Syndrome

Drug	Mechanism
3,4-methylenedioxymethamphetamine (MDMA; ecstasy)	Increase 5-HT synthesis or release Inhibit 5-HT reuptake
Dexamphetamine	Increase 5-HT synthesis or release Inhibit 5-HT reuptake
L-tryptophan	Increase 5-HT synthesis or release
Levodopa	Increase 5-HT synthesis or release
MAO INHIBITORS	
Isocarboxazid	Increase 5-HT synthesis or release Inhibit 5-HT metabolism
Linezolid	Increase 5-HT synthesis or release
Methylene blue	Increase 5-HT synthesis or release Inhibit 5-HT metabolism
Moclobemide (reversible MAO inhibitor)	Increase 5-HT synthesis or release Inhibit 5-HT metabolism
Rasagiline	Inhibit 5-HT metabolism
Selegiline	Increase 5-HT synthesis or release Inhibit 5-HT metabolism
Tranylcypromine	Increase 5-HT synthesis or release Inhibit 5-HT metabolism
SNRIs	
Duloxetine	Inhibit 5-HT reuptake
Milnacipran	Inhibit 5-HT reuptake
Venlafaxine	Inhibit 5-HT reuptake
SSRIs	
Citalopram	Inhibit 5-HT reuptake
Escitalopram	Inhibit 5-HT reuptake
Fluoxetine	Inhibit 5-HT reuptake
Fluvoxamine	Inhibit 5-HT reuptake
Paroxetine	Inhibit 5-HT reuptake
Sertraline	Inhibit 5-HT reuptake
Trazadone	Inhibit 5-HT reuptake
Nefazadone	Inhibit 5-HT reuptake
TCAs	
Amitriptyline	Inhibit 5-HT reuptake
Clomipramine	Inhibit 5-HT reuptake
Imipramine	Inhibit 5-HT reuptake
Nortriptyline	Inhibit 5-HT reuptake
Amantadine	Increase 5-HT synthesis or release

Buprenorphine	Mechanism unknown
Buspirone	Postsynaptic receptor stimulation
Dextromethorphan	Inhibit 5-HT reuptake
Fentanyl	Inhibit 5-HT reuptake and/or other unknown
Hypericum perforatum (St. John's Wort)	Inhibit 5-HT reuptake Inhibit 5-HT metabolism
Lithium	Postsynaptic receptor stimulation
Meperidine	Inhibit 5-HT reuptake and/or other unknown
Metaxalone	Increase 5-HT synthesis or release
Oxycodone	Inhibit 5-HT reuptake and/or other unknown
Sibutramine	Inhibit 5-HT reuptake and/or other unknown
Tramadol	Inhibit 5-HT reuptake and/or other unknown
Ziprasidone	Increase 5-HT synthesis or release Inhibit 5-HT metabolism
Metoclopramide + venlafaxine	Inhibit 5-HT reuptake

5-HT = 5-hydroxytryptamine, MAO = monoamine oxidase, SNRI = serotonin norepinephrine reuptake inhibitor, SSRI = selective serotonin reuptake inhibitor, TCA = tricyclic antidepressant.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The onset of the signs and symptoms of serotonin syndrome may be almost immediate, with approximately 60% of cases presenting within 6 hours after the offending agent has been initiated, the dose increased, or the serum concentration increased by a drug–drug interaction. Serotonin syndrome manifests as a succession of signs and symptoms that progress rapidly over the course of hours and may be highly variable, making identification and diagnosis difficult. Serotonin syndrome is most appropriately thought of as a spectrum of diseases and has been classified into severity categories to aid in earlier or more accurate diagnosis.[535,540,541] Some of the signs and symptoms associated with milder forms of serotonin syndrome (tremor, confusion, incoordination) may be difficult to distinguish from the underlying illness.[535] The more severe symptoms of serotonin toxicity (temperature >38.5°C, myoclonus, diarrhea) are generally observed in overdose situations or when an MAOI or a serotonin-releasing agent is used in combination with an SSRI.[535,542]

Signs and symptoms of serotonin syndrome are listed in **Table 54-19** and may be divided into three categories for patient assessment: autonomic dysfunction (fever, shivering, diaphoresis, diarrhea, tachycardia, labile blood pressure); neuromuscular hyperactivity (clonus, myoclonus, hyper-reflexia, incoordination, tremor); and mental status changes (confusion, agitation, mania possibly progressing to hallucinations, obtundation, coma). Autonomic dysfunction and mental status changes appear in 40% of patients. One half of patients show evidence of neuromuscular hyperactivity.[537,543]

Table 54-19 Signs and Symptoms Associated with Serotonin Syndrome

- Autonomic dysfunction
    - Diaphoresis
    - Diarrhea
    - Hyperthermia
    - Labile blood pressure
    - Shivering
    - Tachycardia
- Electrolyte abnormalities
    - Hypocalcemia
    - Hypomagnesemia
    - Hyponatremia
- Elevated aspartate aminotransferase and alanine aminotransferase
- Elevated creatine kinase
- Leukocytosis
- Mental status changes
    - Agitation
    - Coma
    - Confusion
    - Mania
    - Obtundation
- Neuromuscular hyperactivity
    - Clonus
    - Hyper-reflexia (greater in lower extremities)
    - Incoordination
    - Myoclonus
    - Tremor
- Rhabdomyolysis and myoglobinuria

Sternbach's original criteria for diagnosis of serotonin syndrome are the presence of at least three symptoms temporally related to a suspect medication; other causes have been ruled out; and a neuroleptic agent has not been started or dose increased prior to the onset of signs and symptoms (indicating possible NMS).[535] Problems with the Sternbach criteria may exist and include the weight of mental status changes in the criteria, causing patients with abnormal mental states to be misdiagnosed and a diagnosis of serotonin syndrome to be missed in patients with mild serotonin toxicity. Others have determined that serotonin syndrome may be misdiagnosed in patients with infection using Sternbach's criteria.[466] Because of this lack of sensitivity, diagnostic decision rules have been developed based on the evaluation of 2,222 cases of serotonin overdose reported to the Hunter Area Toxicology Service.[542] These criteria are simpler and include primarily clonus, agitation, diaphoresis, tremor, hyper-reflexia, hypertonia, and hyperthermia. The Hunter criteria have a sensitivity of 84% compared to 75% with the Sternbach criteria. The most important sign in the Hunter criteria is clonus and, if spontaneously present in a patient taking a serotonergic agent, is by itself adequate to make the diagnosis. It is important to note that the diagnostics decision rules were developed from data in patients with overdoses and have not yet been validated to be sensitive and specific for patients with serotonin syndrome at therapeutic doses of serotonergic agents. Fulminant cases of serotonin syndrome may progress to seizures, rhabdomyolysis, renal failure, and death.

Other conditions to consider in the differential diagnosis of serotonin syndrome include infection, sepsis, heat stroke, drug or alcohol withdrawal, sympathomimetic overdose, thyrotoxicosis, anticholinergic fever, and NMS (**Table 54-20**). Although both NMS and serotonin syndrome may present with some common symptoms—including catatonia, tremors, rigidity, and hyperthermia—differences may aid in the diagnosis. Proper diagnosis is essential; bromocriptine is a treatment considered for NMS but should be strictly avoided in patients with serotonin syndrome because it may worsen the condition. The rigidity associated with serotonin syndrome may be less pronounced than that due to NMS and usually occurs in the lower extremities as compared with NMS (described as lead-pipe rigidity) and is not usually limited to the lower extremities. With NMS, the progression of signs and symptoms occurs over the course of days, and there may be a lower incidence of tremors, clonus, and myoclonus. There are usually no gastrointestinal symptoms; however, hyperthermia may be more common. Like NMS, no specific laboratory test exists to confirm a diagnosis of serotonin syndrome.[534] Serotonin concentrations at the synaptic cleft are responsible for toxicity and do not correlate with serum levels.[355] There is some evidence to support the use of urinary 5-HT concentrations as adjuncts to clinical decision making.[544] The most reliable method for appropriate diagnosis is an accurate medication history, including starting dates and doses of medications that increase serotonergic activity and specific information regarding dose escalation, if available.

Table 54-20 Conditions to Consider in the Differential Diagnosis of Drug-Induced Serotonin Syndrome

- Anticholinergic toxicity
- Drug withdrawal (alcohol, benzodiazepines, levodopa)
- Endocrine disorders
- Heat stroke
- Hematologic or solid organ malignancy
- Infection
- Neuroleptic malignant syndrome
- Sepsis
- Sympathomimetic overdose
- Thyrotoxicosis

Table 54-21 Risk Factors for Drug-Induced Serotonin Syndrome

Drug-related

- Higher total daily dose
- Higher-potency agents
- Rapid dose escalation
- Use of concomitant drugs that increase serotonin activity

Patient-related

- Endogenous or acquired defects in MAO activity
- Female sex
- Older age
- Poor metabolizers of SSRIs

MAO = monoamine oxidase, SSRI = selective serotonin reuptake inhibitor.

RISK FACTORS

No patient-specific risk factors for the development of serotonin syndrome have been definitively identified, although increased age and female sex may be predisposing factors (**Table 54-21**). In addition, risk factors may include endogenous or acquired defects in MAO activity that lead to impairment in SSRI metabolism, such as those occurring in patients with cardiovascular diseases (including hypertension and hyperlipidemia), liver disease, pulmonary disease, and in those who smoke cigarettes. Genetic variation in the ability to metabolize serotonergic drugs and activities of MAO isoenzymes may predispose patients to serotonin syndrome. Approximately 7% of individuals are poor metabolizers of SSRIs.[545] This genetic predisposition may enhance a patient's sensitivity to serotonergic agents and increase the propensity for the development of serotonin syndrome.

Other potential risk factors for serotonin syndrome are drug-specific features including drug potency, total daily dose, rapid dose escalation, and use of concomitant agents that may increase serotonin activity or interact with serotonergic agents.

MORBIDITY AND MORTALITY

Most patients fully recover following discontinuation of the causative agent and implementation of supportive care; however, deaths have been reported due to serotonin syndrome.[434,435,442,445,451,457,511] Deaths are reported more often in association with intentional overdose of SSRIs alone or in combination with an MAOI. Mortality from serotonin syndrome ranges between 2–12%.[347] Death from serotonin syndrome generally occurs secondary to multiple organ dysfunction, including rhabdomyolysis leading to renal failure, disseminated intravascular coagulopathy, adult respiratory distress syndrome, and cardiovascular collapse from muscular hyperactivity and hyperthermia. With prompt intervention, however, patients usually recover without long-term sequelae.

PREVENTION

Keys to the prevention of serotonin syndrome are careful initiation and dose escalation of SSRIs, in addition to appropriate patient education regarding drug-induced diseases, drug interactions, and recognition of signs and symptoms of toxicity (**Table 54-22**). SSRI therapy should be initiated at a low dosage and titrated upward slowly, particularly in elderly patients or those with impairment of liver or renal function.

Table 54-22 Approaches to Help Prevent Drug-Induced Serotonin Syndrome

- Adjust dose appropriately for elderly patients and those with hepatic dysfunction or chronic kidney disease
- Be aware of drug interactions and avoid if possible
- Carefully initiate and titrate serotonergic agents
- Carefully switch from one serotonergic agent to another
- Ensure adequate washout period when switching from MAOI to serotonergic agents or serotonergic agents to MAOI

MAOI = monoamine oxidase inhibitor.

Following discontinuation of the culprit drug, a washout period of at least 5–7 days prior to initiating therapy with an MAOI or another SSRI is important; the duration should be determined based on the half-life of the active compound. A washout period of 5 weeks or longer may be necessary for SSRIs with very long half-lives or those with active metabolites such as fluoxetine, sertraline, and clomipramine. In addition, if delayed elimination is suspected in selected patients, a longer drug-free period is warranted. MAOIs inhibit the metabolism of SSRIs and, therefore, directly increase serotonin concentrations at the site of activity. MAOIs should be discontinued at least 4 weeks prior to starting therapy with an SSRI. Moclobemide, a reversible MAOI, requires a much shorter washout period because of its very short half-life; 24 hours may be sufficient. Concomitant use of agents that increase serum serotonin concentrations should be avoided.[534] Appropriate dose adjustments should be made in older patients and in those with renal or hepatic impairment, in addition to closer monitoring of these patients for signs or symptoms of toxicity.

MANAGEMENT

Discontinuation of the offending agent is imperative, as is supportive care, which often results in resolution of signs and symptoms within 24 hours without additional pharmacotherapeutic intervention (**Table 54-23**). Fluid therapy should be implemented in patients in whom diaphoresis has been a significant clinical symptom, in addition to those requiring cooling augmentation.

Although there are no clinical trials that have specifically evaluated the efficacy of any therapeutic intervention for serotonin syndrome, several drugs have anecdotally been reported to be successful. Cyproheptadine, a histamine[1] (H^1) antagonist with nonselective anti–5-HT and anticholinergic properties, has been a successful treatment for serotonin syndrome. In some reports, cyproheptadine has not been found to alter the time course of serotonin syndrome but may relieve signs and symptoms.[546] Others have indicated that cyproheptadine can shorten the duration of some symptoms of serotonin syndrome, including tachycardia, tremor, neuromuscular features, and anxiety.[432] The recommended dose of cyproheptadine for the management of serotonin syndrome is a loading dose of 12 mg followed by 2 mg orally (or via nasogastric tube) every 2 hours until symptoms are controlled then 4–8 mg every 6 hours.[355] In children, 0.25 mg/kg/day has been administered. It has been suggested that these doses are lower than those required to adequately block the 5-HT_{2A} receptors and that 30 mg is a more optimal dose in an adult, potentially explaining some reported treatment failures.[547,548] However, doses of 12–32 mg are likely sufficient to bind 85–95% of serotonin receptors, and alternative treatment or diagnosis should be considered if there has been no response after 32 mg.[347,355] In most cases, the duration of therapy has been no longer than 48 hours, with many patients receiving only a single dose. Cyproheptadine should be avoided in patients in whom anticholinergic toxicity has not been ruled out. The drug may cause hypotension, and fluid therapy may be used, if necessary, for management.

Table 54-23 Management of Drug-Induced Serotonin Syndrome

- Discontinue suspected agent
- Supportive care
  - Cooled fluids
  - Fluid replacement for patients with severe diaphoresis or rhabdomyolysis
  - Surface cooling

- Cyproheptadine 12-mg loading dose followed by 2 mg every 2 hours until symptoms are controlled; 4–8 mg every 6 hours for up to 48 hours for maintenance
- Chlorpromazine 50–100 mg intramuscularly as a single dose, repeat dose every 6 hours if symptoms return; may be given orally if able
- Lorazepam or diazepam may be added to the above therapy in refractory cases as needed to control signs and symptoms
- Benzodiazepine, propofol, or dexmedetomidine infusions may be used for patients requiring sedation and mechanical ventilation
- Neuromuscular blocking agents may be considered for patients with sustained myoclonus or severe hyperthermia

Chlorpromazine has been used in the management of serotonin syndrome, although far less commonly than cyproheptadine and benzodiazepines.[547] In addition to having antimuscarinic effects, chlorpromazine inhibits dopamine, α-adrenergic, and 5-HT_2 receptors. Chlorpromazine is available as an injectable agent and, therefore, may be considered in more severe cases and in cases in which more prompt onset of the effect is desired. Chlorpromazine should not be used in patients with suspected NMS, because dopamine receptor inhibition could worsen the condition. Chlorpromazine should be considered in cases of cyproheptadine failure or in cases with a significant hyperpyrexial or behavioral manifestation. The suggested dose of chlorpromazine is 50–100 mg intramuscularly initially and then every 6 hours. The drug may be administered orally, intramuscularly, or intravenously.[449,547] Single-dose therapy has generally been effective, but the dose may be repeated if signs or symptoms return. Patients receiving chlorpromazine should be adequately hydrated, as it may cause hypotension due to α_2-adrenergic receptor antagonism.[547] Dantrolene has been used successfully in two cases but has also been theorized to increase serotonin levels and decrease metabolism. Routine use in serotonin syndrome is not recommended.[549-551]

Other therapies have been used as either adjunctive therapy or in cases of cyproheptadine failure. Benzodiazepines have been used in the treatment of serotonin syndrome and should be strongly considered in patients with anxiety or agitation. Single-dose therapy has been used, but multiple doses may be administered as needed for management of symptoms. Lorazepam and diazepam have been used alone and in combination with prochlorperazine and propranolol to control the symptoms of serotonin syndrome.[448,489,495,516,520,552] Propranolol has also been used as monotherapy and is thought to possess some 5-HT_{1a}-receptor blocking activity.[508,552,553] Caution should be used when attempting to treat both hypertension or hypotension in this patient population as the blood pressure tends to be quite labile. Preference should be given to short-acting, titratable, agents. Antipsychotics, such as haloperidol, should be avoided for treatment of agitation as they possess anticholinergic activity and may worsen heat dissipation. Propofol has been used for serotonin syndrome as well. One case describes rapid resolution of tachycardia and neuromuscular tone and normalization of reflexes with the use of propofol starting at 10 mcg/kg/min and titrated up to 30 mcg/kg/min in a patient with serotonin syndrome due to intentional dextromethorphan ingestion.[514] Signs and symptoms returned when the propofol was discontinued 2 hours after presentation but again resolved after propofol was restarted. The propofol infusion was continued for an additional 8 hours. Dexmedetomidine has also been used with success in serotonin syndrome.[554] Neuromuscular blockade may be considered for patients with severe serotonin syndrome who experience sustained myoclonus and hyperthermia >41.1°C.[355,452,489] Up to 25% of patients may require intubation, sedation, and mechanical ventilation.[347] Serotonin syndrome should be treated aggressively if symptoms are worsening and in overdose situations, as the disease may be fatal. Signs and symptoms must be monitored closely; Table 54-16 lists important monitoring parameters for patients with serotonin syndrome.

INFORMATION FOR PATIENTS

Patients should be instructed to notify healthcare professionals of all prescription and nonprescription medications and herbal products that they are taking. Healthcare providers should ensure that patients are aware of potential drug interactions, specific medications that should be avoided (such as nonprescription cough medications that contain dextromethorphan), and should instruct patients to ask a pharmacist if they have any questions regarding safe combinations of medications. Clinicians should encourage patients to follow the dosage regimen prescribed closely and accurately and not to increase any doses unless specifically instructed to by the prescriber. Patients should be aware of the signs and symptoms of serotonin syndrome and should be instructed about when to seek medical attention. Development of fever, shivering or diaphoresis, or myoclonus or any mental status changes should prompt patients or caregivers to contact a healthcare facility for further evaluation and treatment.

MALIGNANT HYPERTHERMIA

Malignant hyperthermia is a rare but serious idiosyncratic reaction observed primarily in association with the administration of inhaled anesthetics. Hyperthermia occurs quickly, is often severe, and may be associated with muscle weakness, increased muscular tone, and damage including rhabdomyolysis and metabolic acidosis. Early recognition and intervention are crucial in the management of this drug-induced disease.

Table 54-24 Agents Implicated in Drug-Induced Malignant Hyperthermia

Drug	Incidence	Level of Evidence[a]
ANESTHETICS, INHALED	NK	C
Desflurane[555-563]	NK	C
Enflurane[540-566]	NK	C
Halothane[567-574]	NK	C
Isoflurane[575-589]	NK	C
Methoxyflurane[590]	NK	C
Sevoflurane[572,591-598]	NK	C
DEPOLARIZING SKELETAL MUSCLE RELAXANTS	NK	C
Succinylcholine[472,555-558,563,567, 599-604]	NK	C

NK = not known.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

CAUSATIVE AGENTS

Drugs that have been reported to cause malignant hyperthermia are listed in **Table 54-24**.[555-604] Inhalational anesthetics, with the exception of nitrous oxide, and depolarizing neuromuscular blocking drugs (skeletal muscle relaxants) are the drug classes most frequently implicated in the development of malignant hyperthermia. The agents most commonly reported to cause malignant hyperthermia include halothane, enflurane, isoflurane, and succinylcholine. Succinylcholine may increase the risk, worsen the severity, and shorten the onset time of malignant hyperthermia when used in combination with inhaled anesthetics.[555-558] Succinylcholine may also cause malignant hyperthermia independently.

EPIDEMIOLOGY

Malignant hyperthermia is a genetically linked, life-threatening condition that is observed in all ethnic groups and is more common in men than in women.[605,606] On average, malignant hyperthermia may be observed with the third exposure to a triggering agent, although it is possible to occur with the first use in a susceptible patient. Malignant hyperthermia is more common in children under 15 years of age, with an incidence of 1 in 8,000 to 1 in 15,000, as compared with an estimated incidence of 1 in 40,000 to 1 in 150,000 in adults.[605-607]

MECHANISMS

Heterogenic mutations in the ryanodine receptor (*RYR1*) and dihydropyridine receptor (*CACNA1S*) genes, and other mutations yet to be fully characterized, are involved in the etiology of malignant hyperthermia.[608] The RYR1 receptor is a calcium channel located in the sarcoplasmic reticulum membrane. Disruptions in this channel lead to malignant hyperthermia susceptibility. Although not all of the genetic loci involved have been identified, it is known that malignant hyperthermia occurs because of a defect in the regulation of intracellular calcium metabolism, specifically the proteins involved in excitation–contraction coupling, the dihydropyridine–ryanodine receptor complex, such that the sarcoplasmic reticulum of skeletal muscle releases calcium inappropriately in response to an inducing drug.[608-610] The increase in calcium concentration may lead to unregulated actin and myosin cross-bridging, resulting in sustained muscle contraction. This muscle rigidity results in increased oxygen consumption, hypoxia, excessive heat production and muscle damage, and the clinical presentation of malignant hyperthermia.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Although highly variable, the classic presentation of malignant hyperthermia is sudden, severe hyperthermia with muscle rigidity, metabolic acidosis, and rhabdomyolysis (**Table 54-25**). The onset of symptoms is very rapid, beginning within minutes to several hours after drug initiation and up to 1 hour after discontinuation.[611] Hyperthermia may be delayed and may occur after other symptoms (rigidity and tachycardia). Temperature may acutely increase in excess of 1°C every 5 minutes up to maximum temperatures of 46°C or higher.[605,612] With the more modern use of less potent inhalational agents, this course has been described to be more insidious or attenuated, with a delayed onset and slower clinical progression.[613,614]

Table 54-25 Signs and Symptoms Associated with Drug-Induced Malignant Hyperthermia

- Muscle pain, weakness in jaw, chest, and extremities
- Muscle contraction

- Initial signs
  - Hyperthermia
  - Increase in end-tidal carbon dioxide
  - Masseter-muscle rigidity
  - Metabolic acidosis
  - Tachycardia
- Signs as syndrome progresses
  - Cardiac dysrhythmias
  - Hyperkalemia, hypercalcemia, hyperphosphatemia
  - Hypotension
  - Metabolic and respiratory acidosis
  - Pulmonary edema
  - Rhabdomyolysis and renal failure

Early signs and symptoms of malignant hyperthermia may include masseter-muscle rigidity (particularly in children), tachycardia, and a sudden, dramatic increase in end-tidal carbon dioxide ($ETCO_2$) to >55 mm Hg. The increase in $ETCO_2$ is a sensitive indicator of the disease but may be less dramatic and more gradual in patients who do not receive succinylcholine. Muscle pain, weakness, and increased tone in the jaw, chest, and extremities may occur and are often severe and refractory to therapy with neuromuscular blocking agents. Muscle contraction and subsequent muscle damage results in the release of CK and myoglobin, which may contribute to the development of rhabdomyolysis and renal failure.

As the syndrome progresses, pulmonary edema, hypotension, heart failure, electrolyte abnormalities (hyperkalemia, hypercalcemia, hyperphosphatemia), metabolic and respiratory acidosis (pH <7.25 and partial pressure of CO_2 [$paCO_2$] >60 mm Hg), and the resultant dysrhythmias may be observed. The $paCO_2$ may exceed 100 mm Hg and pH may decline to <7 in severe cases. A presumptive diagnosis is made based on signs and symptoms temporally related to the administration of inhalational anesthetics or succinylcholine. Definitive diagnosis of malignant hyperthermia requires the European in vitro contracture test (IVCT), or the modified caffeine halothane contracture test (CHCT) used in North America. These tests require a muscle biopsy, which is exposed to halothane or caffeine to determine the contracture threshold. The patient is diagnosed as being susceptible to malignant hyperthermia based on the threshold at which the muscle is reactive.[615] This test is not necessary as a confirmation of diagnosis for patients in whom the typical signs and symptoms have developed.[616,617] Rather, optimal use of this test is as a screen for susceptible individuals (based on family history) prior to use of triggering agents. DNA testing is also an option for specific, at-risk individuals; guidelines for testing have been published.[618,619]

In addition, a clinical grading scale for malignant hyperthermia has been developed to aid in the diagnosis and for predicting susceptibility to this drug-induced disease.[620] This scale was developed by an international panel of malignant hyperthermia experts using anonymous polling and questionnaires to minimize bias and subjective influence. Clinical indicators were developed with points for each indicator as well as scoring rules. The clinical grading scale allows for objective determination of the likelihood of a malignant hyperthermia diagnosis and is an extremely valuable tool. Differential diagnosis includes hypoxia due to atelectasis, bronchial obstruction, sepsis, and pulmonary mechanical failure, although these conditions are not generally associated with the degree of temperature elevation that occurs in patients with malignant hyperthermia (Table 54-26).

Table 54-26 Conditions to Consider in the Differential Diagnosis of Drug-Induced Malignant Hyperthermia

- Atelectasis
- Bronchial obstruction
- Drug withdrawal (alcohol, benzodiazepines, levodopa)
- Endocrine disorders
- Heat stroke
- Hematologic or solid organ malignancy
- Infection
- Pulmonary mechanical failure
- Sepsis

Table 54-27 Risk Factors for Drug-Induced Malignant Hyperthermia

- Eye, head, or neck surgeries
- Family history of malignant hyperthermia
- Male sex
- Muscular dystrophies/diseases
- Young age (<15 yr)

RISK FACTORS

Malignant hyperthermia is an idiosyncratic reaction and therefore is difficult to predict. However, because the disorder is genetically linked, patients with a family history of malignant hyperthermia are at significantly higher risk than those without a family history (Table 54-27). Younger patients, males, and those with central core disease tend to be predisposed to this drug-induced disease. The type of surgical procedure may also be associated with differences in incidence of malignant hyperthermia. Eye, head, neck, and musculoskeletal surgeries are associated with the highest risk.[606] Certain muscular diseases, including Duchenne muscular dystrophy, Becker's muscular dystrophy, Wolf–Hirschhorn syndrome, kyphoscoliosis, myotonic dystrophy, and others have been linked to a predisposition to malignant hyperthermia.[621,622]

Elevated resting serum CK concentrations have been used in the past as a means to try to identify patients at risk for malignant hyperthermia and research exploring the relationship between resting CK levels and malignant hyperthermia is ongoing.[623,624] Currently, however, use of this screening method is not routinely recommended.[625]

MORBIDITY AND MORTALITY

In the past, mortality associated with malignant hyperthermia was high, exceeding 60%.[626,627] With early recognition and appropriate intervention, mortality has decreased substantially and currently may be as low as 7%.[628-630] Early implementation of therapy with dantrolene and shorter duration of anesthesia (<30 minutes) may be associated with enhanced survival (87%); patients who receive anesthesia for longer than 30 minutes have been found to have lower survival rates (43–61%).[631] The prognosis has been found to be worse for men than for women for unknown reasons, although an increased muscle mass in men may be contributory.[605,606]

The risk of death has also been associated with the maximum temperature, the rate of rise of temperature, and the duration of hyperthermia.[631] Hyperthermia may cause agitation, confusion, disorientation, combativeness, lethargy, seizures, coma, and death. Rhabdomyolysis and disseminated intravascular coagulation may lead to acute tubular necrosis. Volume depletion, tissue injury, and hypoxia may lead to shock, organ dysfunction, and organ failure. Cardiac dysrhythmias, such as ventricular fibrillation due to hyperkalemia, may occur, are often difficult to treat, and may result in cardiac arrest and death.[632,633]

PREVENTION

The key to the prevention of malignant hyperthermia is avoidance of the use of inhaled anesthetics and depolarizing neuromuscular blocking agents in patients with a personal history or a strong family history of the condition (**Table 54-28**) and flushing of the anesthesia machine prior to use in these individuals. Appropriate patient screening regarding family members with a history of malignant hyperthermia or death during surgery or general anesthesia should be performed. Patients at risk may be given the opportunity for an IVCT or CHCT to determine susceptibility to triggering agents. Drugs that have been used safely in susceptible patients (those with a history of malignant hyperthermia or those with a strong family history) include nitrous oxide, bupivacaine, barbiturates, opiates, propofol, and nondepolarizing muscle relaxants.[599,634,635]

Table 54-28 Approaches to Help Prevent Drug- Induced Malignant Hyperthermia

- Avoid use of triggering agents, if possible, in selected patients
- Carefully screen patient and family members prior to use of anesthesia
- Use genetic testing in specifically targeted patients
- Use in vitro contracture test in appropriate patients
- Use medical alerting devices in patients with a history of malignant hyperthermia or who are at high risk
- Use nitrous oxide, bupivacaine, barbiturates, opiates and nondepolarizing skeletal muscle relaxants

It has been suggested that prophylaxis with oral dantrolene may be effective for the prevention of malignant hyperthermia in susceptible individuals, although no data from randomized, controlled trials are available.[636-639] In one study, oral dantrolene was administered at a dose of 5 mg/kg in three or four divided doses with the last dose administered 4 hours preoperatively to 10 patients who were susceptible to malignant hyperthermia.[637] None of the patients experienced malignant hyperthermia, but some experienced drowsiness and weakness due to dantrolene administration.[636] Malignant hyperthermia has also been prevented via the administration of dantrolene 100 mg 4 times daily for 3 days before surgery and 100 mg on the day of surgery.[638] Two cases of malignant hyperthermia despite oral dantrolene administration have been reported, although in these cases the administered doses were lower than recommended.[640,641] Dantrolene prophylaxis is not expected to be completely successful and may cause significant muscle weakness resulting in temporary disability, a factor that should be considered in the decision about whether to attempt prophylaxis.[639,642,643] Several cases have been reported in which patients were successfully anesthetized without prophylactic administration of dantrolene when triggering agents were not used and patients were monitored very closely.[635,644] Currently, the use of dantrolene prophylaxis in susceptible patients is not recommended because the risk of malignant hyperthermia when triggering agents are avoided is low and because of the potential adverse effects associated with dantrolene.

MANAGEMENT

Early recognition and intervention is crucial. All suspected medications must be immediately discontinued, the surgical procedure stopped as soon as feasible, and the patient removed from the anesthesia machine and hyperventilated with 100% oxygen (**Table 54-29**). Ongoing anesthesia can be provided using intravenous anesthetics, opioids and nondepolarizing muscle relaxants. Control of fever, acidosis, hypermetabolism, and hypercarbia is imperative. Administration of intravenous fluids will aid in the prevention of acute tubular necrosis and metabolic acidosis from the hypermetabolic state and in maintaining cardiac output. Hypercarbia and hypoxemia should be treated with aggressive oxygen management and hyperventilation. Rapid cooling measures such as cooling blankets, ice packs, ice water gastric lavage, and intravenous fluids should be implemented. Shivering may occur from rapid temperature decrease and should be treated with chlorpromazine, opioids, benzodiazepines, and when necessary, paralysis with mechanical ventilation for severe, refractory shivering to control oxygen utilization. In addition to fluid resuscitation and electrolyte and acid–base management, patients may require treatment with procainamide, amiodarone, or β-blockers to control tachydysrhythmias that may develop. Calcium channel blockers should not be used due to a potential for hyperkalemia in association with dantrolene administration.

Table 54-29 Management of Drug-Induced Malignant Hyperthermia

- Discontinue suspected agent
- Cooling measures and other supportive care
    - Cooled intravenous fluids
    - Ice water nasogastric or rectal lavage
    - Surface cooling
- Fluid and electrolyte replacement as needed
- Continuous ventilatory management
- Dantrolene 2.5 mg/kg intravenously as needed to control signs and symptoms (up to 10 mg/kg; doses up to 30 mg/kg may be used in severe, refractory cases)
- Nondepolarizing neuromuscular blocking drugs, benzodiazepines, chlorpromazine as needed for refractory shivering or rigidity

Dantrolene is a specific ryanodine receptor antagonist that inhibits calcium release from the endoplasmic reticulum, which dramatically alters the course of malignant hyperthermia. In one study of 11 patients with malignant hyperthermia to whom dantrolene was administered, 100% of patients survived.[645] In one retrospective medical record review, the mortality rate was 8.9% in 79 patients who received intravenous dantrolene prior to cardiac arrest, as compared to a mortality rate of 25.4% in 375 patients who did not receive dantrolene—a 16.6% absolute reduction in mortality.[631] Rapid dantrolene administration after recognition of the syndrome is critical, as a favorable outcome is related to a shorter elapsed time from symptom onset to time of drug administration. Dantrolene should be administered as an intravenous dose of 2–2.5 mg/kg initially, repeated as necessary up to 10 mg/kg until signs and symptoms begin to abate, which is expected to occur within minutes of dantrolene administration. Higher doses of up to 30 mg/kg may be administered in severe, refractory cases although reaching these higher doses without improvement suggests the diagnosis of malignant hyperthermia should be reassessed.

Two formulations of dantrolene are currently available, a 20-mg vial and a 250-mg vial. Both preparations require reconstitution with sterile water for injection; no other diluent is recommended. The 20-mg vial requires 60 mL of sterile water and shaking until a clear solution is achieved, and the 250-mg vial requires 5 mL of sterile water and will result in an orange suspension. Both are to be administered via intravenous push for emergency management of malignant hyperthermia. It should be noted that the 250-mg vial is currently more costly but may be more convenient in the critical setting of malignant hyperthermia because only one vial and 5 mL of sterile water are needed compared to 10–12 vials of the 20-mg per vial and 60 mL sterile water for each vial. The currently recommended initial doses are higher than those that were recommended previously (1 mg/kg) because of diminished circulation in patients with malignant hyperthermia and so a more aggressive approach is warranted.[569,646] The duration of treatment in the cases reported has varied considerably, from single-dose therapy to multiple days of therapy.

After the patient has stabilized, dantrolene may be administered orally at a dose of 50–300 mg per day in divided doses or 1–2 mg/kg 4 times daily for several days (at least 36 hours) to prevent recurrence.[647] Dantrolene has been used successfully and safely in pregnant patients who are susceptible to malignant hyperthermia and are undergoing caesarean section.[648-655] Dantrolene may cause dizziness, diplopia, dysarthria, a sensation of swelling of the eyes and tongue, and subjective (but not objective) weakness.[569,631,643] Patients have been successfully managed without the use of dantrolene with only supportive and cooling therapies but this approach is not recommended.[614,656,657]

Close monitoring for improvement of signs and symptoms as well as any signs of recurrence is important for a successful outcome in patients with malignant hyperthermia. Appropriate monitoring parameters are listed in **Table 54-30**. Patients who may be susceptible but are not given triggering agents can be safely monitored with the standard procedures used for nonsusceptible patients.[658]

Table 54-30 Monitoring Parameters for Patients with Drug-Induced Malignant Hyperthermia

- Blood gases
- Coagulation profile
- Continuous cardiac rhythm
- Continuous central temperature
- End-tidal carbon dioxide
- Heart rate
- Mental status

- Metabolic panel including serum carbon dioxide concentration
- Muscle rigidity
- Pulse oximetry
- Respiratory rate
- Serum creatinine and blood urea nitrogen concentrations
- Serum creatine kinase concentrations
- Serum electrolyte concentrations
- Urine myoglobin concentrations

INFORMATION FOR PATIENTS

Patients should be questioned regarding a history of malignant hyperthermia or a problem with anesthesia and should be instructed to alert all healthcare professionals of this risk. In addition, family members of patients with a prior episode should be made aware of their potential risk. Patients at risk should be given the opportunity for an IVCT to determine susceptibility to triggering agents. Various options for anesthesia, as well as the risks and benefits of those options in addition to prophylaxis with dantrolene, should be discussed with patients at risk prior to any surgery. A medical alerting device is recommended for those with a history of malignant hyperthermia or who have a significant family history and positive IVCT in the event that emergency surgery is needed. Finally, patients should be offered the opportunity to register with the Malignant Hyperthermia Association of the United States (MHAUS) by calling 1-800-MH-HYPER (1-800-644-9737) or visiting the website at www.mhaus.org. The website provides patient and healthcare professional information in addition to resources for susceptibility testing, hotline contact information, and for obtaining an Emergency Medical Identification Card.

HYPOTHERMIA

Drug-induced hypothermia occurs much less frequently than hyperthermia. Hypothermia can be defined as a core body temperature <35°C.[572] Although drug-induced hypothermia can occur with certain prescription drugs, it is most commonly associated with illicit drug use.

CAUSATIVE AGENTS

Baclofen, GHB, and gamma-butyrolactone (GBL), is converted to GHB after ingestion, are structurally related to GABA and may cause hypothermia in overdose.[660-667] GHB is best known as the “date rape” drug but is also contained within body-building supplements and marketed for recreational purposes. GBL is found in industrial and household solvents and other products, including dietary supplements marketed for sleep and for enhancing sexual and athletic performance.

Although the U.S. Food and Drug Administration requested a voluntary recall of GBL-containing products in 1999, it may still be available via the Internet in products labeled as dietary supplements listed as “dihydro-2(3H)-furanone,” “4-butanolide,” “2(3H)-furanone, dihydro,” “tetrahydro-2-furanone,” and “butyrolactone gamma.” Street names for both GHB and GBL are listed in **Table 54-31**. Drugs associated with hypothermia are listed in **Table 54-32**.[660-667,669-679] It has been suggested that antipsychotics can cause hypothermia but clear data to substantiate the claim are lacking.[668] Additional data continue to emerge indicating hypothermia related to antipsychotics to be a true effect, although not well understood.[669,670,674-677,679] Atypical antipsychotics account for 55% of the cases of reported drug-induced hypothermia.[668] Reports also exist of patients experiencing hypothermia following general anesthesia secondary to vasodilation, impaired shivering, and cool operating rooms.[680] Additional reports implicate intrathecal morphine and some benzodiazepines as potential culprits.[659,668,671,673,678]

Table 54-31 Street Names for Gamma-Hydroxybutyrate and Gamma-Butyrolactone

Gamma-hydroxybutyrate (GHB)

- Bedtime Scoop
- Cherry Meth
- Easy Lay
- Fantasy
- “G”
- G-juice
- GBH
- G-riffic
- Gamma Oh
- Gamma Ten
- Georgia Home Boy
- Gook
- Great Hormones at Bedtime
- Grievous Bodily Harm
- Jib
- Liquid E
- Liquid Ecstasy
- Liquid G
- Liquid X
- Organic Quaalude
- Salty Water
- Scoop
- Sleep
- Sleep-500
- Soap
- Somatomax
- Vita G

Gamma-butyrolactone (GBL)

- Blue Nitro
- Blue Nitro Vitality
- Fire Water
- GH Revitalizer
- Gamma G
- Re-energize
- Remforce
- RenewTrient
- Revivarant
- Revivarant G

EPIDEMIOLOGY

The incidence of drug-induced hypothermia is unknown. With regard to hypothermia related to antipsychotic use, a 2007 article analyzing the World Health Organization international database found 480 cases of antipsychotic-related hypothermia. Oral risperidone was the most common agent associated, with 27% of cases, and clozapine second, with 14%.[668]

MECHANISMS

Temperature balance occurs via the anterior hypothalamus, with stimulation and inhibition from a variety of neurotransmitters in a complex process. Dopamine and serotonin receptors are involved in thermoregulatory balance. Although both D_1 and D_2 receptor subtypes are involved in temperature regulation, the more prominent effect of dopamine receptor stimulation is lowering of temperature, and the more prominent effect of dopamine receptor antagonism is that of elevating temperature. Cannabinoid and opioid-induced hypothermia is mediated via dopaminergic pathways. In addition, opioids may decrease body temperature through agonism of opiate receptors in the hypothalamus and vasodilation. A relative increase in serotonin concentrations increases temperature. GABA and baclofen inhibit the release of excitatory neurotransmitters, including serotonin and dopamine, resulting in a net effect of hypothermia.

Table 54-32 Agents Implicated in Drug-Induced Hypothermia

Drug	Incidence	Level of Evidence[a]
Baclofen[663]	NK	C
Cannabinoids[666]	NK	C

Chlorpromazine[669,670]	NK	C
Clobazam[671]	NK	C
Clozapine[659,668,670]	NK	C
Diazepam[672,673]	NK	C
Gamma-butyrolactone (GBL)[666]	NK	C
Gamma-hydroxybutyrate (GHB)[660-662,664,667]	NK	C
Haloperidol[674,675]	NK	C
Olanzapine[676,677]	NK	C
Opioids[666,678]	NK	C
Promethazine[670]	NK	C
Risperidone[668,679]	NK	C
Thioridazine[675]	NK	C

NK = not known.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

Antipsychotic-induced hypothermia is poorly understood. Although dopaminergic and serotonergic antagonism would seemingly lead to hyperthermia as in NMS, these agents have been implicated on multiple accounts to cause hypothermia. Due to the propensity of atypical antipsychotic agents to produce more hypothermia than typical agents, it is proposed that there is some component mediated by serotonin because atypical agents have stronger 5-HT_2 antagonism.[668] Additional theories suggest that agents such as chlorpromazine, clozapine, promethazine, and risperidone lower body temperature through alpha sympatholytic impairment of skin vessel vasoconstriction thus increasing heat dissipation.[670] Impaired vasoconstriction has also been hypothesized for some benzodiazepine-mediated cases.[679] Antipsychotic agents may also indirectly create temperature disturbances by altering the behavioral response to environmental temperature changes.[659] The intricacy in the balance of factors is not fully understood, highlighted by the ability of the same antipsychotic being capable of producing both hyperthermia and hypothermia. Antipyretic agents such as acetaminophen, aspirin, and other nonsteroidal anti-inflammatory drugs decrease temperature in febrile patients in whom the thermoregulatory set point has been raised. However, these drugs have no effect on temperature in afebrile patients.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Drug-induced effects other than hypothermia associated with overdose of these agents are generally more clinically significant (**Table 54-33**). In one series of cases of intentional baclofen overdose, it was reported that six of eight patients were hypothermic (temperature ≤35.5°C).[663] Other clinical signs included bradycardia, hypertension, hyporeflexia, apnea requiring intubation, and coma. Two patients experienced seizures. Hypertension and seizures were managed, and patients were treated for the possibility of co-ingestion of other drugs. Otherwise, treatment was supportive. All patients recovered without permanent sequelae within 5 days of ingestion.

Seventy cases of GHB overdose in which body temperature was reported have been reviewed.[660] The mean (±SD) initial temperature was 35.8 ± 1.1°C (range, 32–39); 48 patients had an initial temperature of ≤36°C, and 22 had an initial temperature of ≤35°C. Alcohol or other drugs were usually co-ingested, impairing detection of specific drug-induced signs and symptoms. In addition to hypothermia, commonly reported clinical signs and symptoms of GHB and GBL ingestion include hypotension, respiratory depression, central nervous system depression, bradycardia, nausea, vomiting, combativeness, and tremors or twitching. Co-ingestion of other substances must be strongly considered in the differential diagnosis as well as hypothyroidism.

Table 54-33 Signs and Symptoms of Drug-Induced Hypothermia

- Bradycardia
- Chills
- Combativeness
- Decreased motivation
- Hyporeflexia
- Hypotension
- Hypothermia
- Nausea
- Personal neglect
- Respiratory depression
- Tremors or twitching
- Vomiting
- Weight loss

Patients with hypothermia secondary to antipsychotic use may present with nonspecific symptoms similar to those of their underlying disease, such as decreased motivation, poor personal hygiene, hostility, weight loss, and possibly chills.[659,674,676]

RISK FACTORS

There are no known risk factors for the development of drug-induced hypothermia related to illicit drugs. Based on the cases reported, the disease appears to be dose-related, and therefore individuals taking these products and drugs in larger quantities or more frequently may be at higher risk. Organic brain disease such as mental retardation and epilepsy appear to place patients treated with antipsychotic agents at higher risk for hypothermia.[681] Patients with schizophrenia have also been shown to display impaired thermoregulation at baseline without medication. Levels of the thermoregulatory peptide neurotensin are decreased in the cerebral spinal fluid of these patients but increase to normal levels with antipsychotic treatment.[682,683] It is unclear whether a diagnosis of schizophrenia would place a patient at higher risk for drug-induced hypothermia. Patients also appear to be at higher risk for hypothermia during the first few days following the initiation of a new antipsychotic regimen or dosage increase.[684]

MORBIDITY AND MORTALITY

Most patients with drug-induced hypothermia recover without permanent sequelae. However, severe symptoms have developed in some, including seizures, apnea, and coma.[660-665] In summaries of reported GBL overdose cases (41 patients) and GHB cases at a single facility (88 patients), no deaths were reported.[660,664] Most patients fully recover without significant intervention within hours of ingestion. Deaths have rarely been reported in other cases of sole GHB ingestion.[665,667] Most cases of antipsychotic-induced hypothermia resolve within 24–36 hours.[671]

PREVENTION

The key to prevention of illicit drug-induced hypothermia is avoidance of the use of these drugs. Tighter control of the contents of products available over the Internet and patient awareness are advisable. Because baclofen is often used in children and adolescents, secured storage may help reduce the occurrence of hypothermia due to overdose of this drug. There is no clear way to reduce the risk of antipsychotic-induced hypothermia. Atypical agents appear to have a higher incidence of hypothermia but have a better safety profile in general compared to typical agents.

MANAGEMENT

Drug-induced hypothermia secondary to ingestion of these drugs is generally mild and does not require specific intervention apart from cessation of the offending substance. If hypothermia is secondary to antipsychotic use and continued therapy is needed, reinitiation at a lower dose or an alternative agent is recommended.[671,674] In one rare case of persistent hypothermia following intrathecal morphine administration, temperature normalized following a single oral dose of lorazepam. Other causes of hypothermia should be evaluated and treated, if applicable. Although warming patients is usually not necessary, if hypothermia is severe or if large amounts of fluids are to be administered, blankets and warmed fluid replacement to prevent further body cooling may be used. Supportive measures should be implemented, including intubation and mechanical ventilation (in patients with severe respiratory depression or for airway protection) as well as cardiac monitoring for arrhythmias. Concomitant management of known or suspected co-ingestants is imperative; toxicology screens should be performed and blood alcohol concentrations should be determined.

INFORMATION FOR PATIENTS

Patient information should include warnings about the use of illicit drugs, particularly those that may be available through the Internet, health facilities, and other sources with the potential for hidden ingredients. Patients who are hospitalized because of illicit drug use should receive drug counseling prior to discharge and be offered information regarding treatment programs. Patients or caregivers of those receiving antipsychotic therapy should notify healthcare providers in the event of declining mental status or motivation. Patients should also maintain an accurate history of any adverse drug events in their health history and offer this information to healthcare providers.

CHAPTER 55

Ototoxicity

Monica L. Miller

Ototoxicity is a broad term defining toxicity induced by certain drugs or chemicals that affect the cochlea, vestibular cells, or the acoustic nerve.[1-3] Damage to these structures can lead to a sensorineural hearing loss.[4] This type of hearing loss can be associated with aging as well as medications.[4] Symptoms associated with ototoxicity include hearing loss, tinnitus, hyperacusis, and vertigo.[5] Hearing loss can range from partial to complete and may occur in one or both ears. Tinnitus is defined as hearing a sound without a source.[6] Hyperacusis is defined as auditory acuity that may be associated with painful sensitivity or sounds that are "normal volume" that are so loud they are painful.[7] Vertigo is a symptom defined as illusionary movement where patients may feel as if they or surrounding objects are moving when in actuality, both are stationary.[6] Patients with tinnitus often report hearing buzzing, ringing, or hissing sounds. Vertigo and tinnitus, like hearing loss, range in severity.

CAUSATIVE AGENTS

Drugs that have been reported to cause ototoxicity are listed in **Table 55-1**.[1,8-242] Common drug classes associated with auditory toxicity include aminoglycosides, diuretics, nonsteroidal anti-inflammatory drugs (NSAIDs), and platinum-based chemotherapeutic agents. Otic administration of aminoglycoside antibiotics is not generally associated with ototoxicity except in patients with a perforated tympanic membrane.[243]

The data regarding the ototoxic potential of vancomycin are mixed. In the past, early formulations had impurities that may have caused ototoxicity and could have accounted for a higher reported incidence.[244,245] Further, vancomycin and aminoglycosides have frequently been administered concomitantly to patients with serious infections.[244,245] Today, reports of vancomycin ototoxicity are rare, except when patients have other risk factors.[243] A study of patients receiving only vancomycin revealed a mild, reversible hearing loss in 3% of patients.[232]

Opioids and opiates have also been reported to cause ototoxicity, principally sensorineural hearing loss that can either be reversible or permanent.[4,174,246] Methadone is the most commonly implicated, but there are also reports of ototoxicity with codeine–acetaminophen, hydrocodone–acetaminophen, morphine, oxymorphone, and propoxyphene.[4,10,246] Ototoxicity has been associated with both acute and chronic use of these medications. Methadone, in particular, has been associated with bilateral sensorineural hearing loss. In most cases, ototoxicity resolved after discontinuation of the drug, although one report noted persistent hearing loss 9 months later.[4,246-248] There are several case reports of heroin-induced ototoxicity leading to reversible or permanent hearing loss.[249-251]

Table 55-1 Agents Implicated in Drug-Induced Ototoxicity[1,8-242]

Drug	Incidence	Level of Evidence[a]
Abacavir[8,b]	NK	C
Acetaminophen[10,d]	NK	C
Acetazolamide[9,c]	NK	B
Alfuzosin hydrochloride[11,b]	2%	B
Amikacin[12-16,d]	0–28.5%	B
Aminocaproic acid[18,c]	NK	B
Aminophylline[19,20,b]	NK	B
	NK	C

Amiodarone[17,b]		
Amitriptyline[21,22,c,d]	NK	B
Amlodipine[23,b]	0.1–1%	C
Amphotericin B[24,d]	NK	B
Ampicillin[25,d]	NK	C
Aripiprazole[26,b]	1–10%	B
Aspirin[27-30,b,d]	0.3–1.7% 50–75% if dose >4 g/day	B
Atazanavir[31,b]	0.1–1%	B
Atropine[32,d]	NK	C
Azithromycin[1,33-36,d]	14–26% (in patients with HIV)	C
Aztreonam[37,d]	3%	C
Bacitracin[38,c]	NK	C
Bleomycin[39,d]	NK	B
Bromocriptine[40,b]	NK	B
Bumetanide[41,b,c]	1.1–1.7%	B
Bupivacaine[42,c]	NK	B
Bupropion[43,44,d]	NK	C
Candesartan cilexetil[45,b]	NK	A
Capreomycin[46,d]	NK	B
Captopril[47,b]	NK	B
Carbamazepine[48,c,d]	0.2%	B
Carboplatin[49-52,d]	15–82%	B
Carvediolol[53,b]	NK	B
Chloramphenicol[55,d]	NK	B
Chlorhexidine[56,d]	NK	B
Chloroquine[57,c,d]	NK	B
Chlorthalidone[58,c]	NK	B
Ciclopirox[54,d]	NK	C
Cidofovir[59,d]	NK	C
Ciprofloxacin[60,b]	NK	B
Cisplatin[61-66,d]	4–97%	B

Clarithromycin[67,68,c]	NK	C
Clindamycin[69,d]	NK	C
Clonazepam[70,b]	NK	B
Codeine[9,d]	NK	C
Cycloserine[71,b]	NK	B
Cyclosporine[72,d]	2%	B
Cytarabine[73,b]	NK	B
Danazol[74,d]	NK	C
Dantrolene[75,b]	NK	B
Dapsone[76,c]	NK	B
Deferoxamine[77,78,c,d]	29–50%	B
Desipramine[79,c]	NK	B
Diazepam[80,b,c,d]	NK	B
Diclofenac[82,b,c]	NK	B
Didanosine[83,d]	NK	C
Diflunisal[84,c]	1–3%	B
Diltiazem[85,b]	NK	B
Donepezil[86,b]	10%	B
Doxepin[87,c]	NK	C
Doxycycline[88,b]	up to 77%	B
Efavirenz[89,90,d]	NK	C
Enalapril[91,92,d]	NK	C
Enalaprilat[92,d]	NK	C
Erlotinib[93,d]	NK	C
Erythromycin[35,94,95,b,c,d]	32%	B
Ethacrynic acid[96,b,c]	NK	B
Ethionamide[97,d]	NK	C
Etidronate[98,99,c,d]	NK	C
Etodolac[82,c]	NK	B
Famotidine[100,b,c]	NK	C
Fenofibrate[101,b]	NK	C
Fenoprofen[82,c]	NK	B

Flecainide[102,c]	3%	B
Fludarabine[103,d]	NK	C
Fluoxetine[104,b]	NK	C
Furosemide[96,105,106,b,c]	3–6.4% 50–100% if injected rapidly	B
Gentamicin[107-120,d]	0–63%	B
Glycerin[121,d]	NK	C
Hepatitis B vaccine[122,d]	NK	C
Hyaluronidase[128,b]	NK	B
Hydrochlorothiazide[c,d]	NK	B
Hydrocodone–acetaminophen[123,124,d]	NK	C
Hydroxychloroquine[125-127,d]	NK	C
Ibuprofen[82,b,c]	NK	B
Ifosfamide[129,d]	NK	B
Imipramine[130,c]	NK	C
Indomethacin[82,b,c]	NK	B
Interferon[131,132,c,d]	39.5%	B
Irbesartan[133,b]	NK	A
Isoniazid[134,b,c]	16.6%[e]	B
Isotretinoin[135,c,d]	NK	C
Itraconazole[136,b]	NK	B
Kanamycin[137,d]	5–26.9%	B
Ketoconazole[138,c]	NK	B
Ketoprofen[82,c]	NK	C
Ketorolac[139,d]	NK	C
Lacosamide[140,b]	NK	B
Lamivudine[141,142,d]	NK	C
Lamotrigine[143,144,b]	NK	B
Leflunomide[145,c]	NK	C
Lidocaine[146,c]	NK	B
Lisinopril[147,b]	NK	B
Lithium[148,c]	NK	B

Lorazepam81,b,c,d	NK	B
Lovastatin149,b	NK	C
Mannitol150,d	NK	C
Mefenamic acid151,b,c,d	NK	C
Mefloquine152,c,d	NK	C
Methylergonovine153,b,c	NK	C
Metronidazole154,d	NK	C
Minocycline155,156,b	14–60%	B
Minoxidil157,d	NK	C
Mirtazapine158,c,d	1%	B
Misoprostol159,b,c,d	NK	C
Moxifloxacin160,d	NK	C
Muromonab-CD3161,d	NK	C
Nabumetone162,b	NK	C
Naproxen163,d	NK	C
Neomycin164,d	up to 60%	B
Nicardipine85,165,b,c	NK	C
Nicotine166,b	NK	B
Nifedipine85,165,b,c	NK	B
Nimodipine85,165,c	NK	B
Nitroprusside167,168,d	NK	B
Norfloxacin169,c,d	NK	C
Nortriptyline80,c	NK	C
Omeprazole170,c	<1%	C
Oxaprozin171,c,d	<1%	B
Oxcarbazepine172,b	NK	B

Paroxetine177,b	NK	B

Phenobarbital[178,b]	NK	B
Phenylbutazone[82,b,c,d]	NK	B
Phenytoin[179,b]	NK	B
Piroxicam[180,181,c,d]	NK	C
Polymixin B[182,b]	NK	B
Potassium iodide[183,d,g]	NK	C
Prazosin[184,c]	1%	B
Prednisolone[185,b]	NK	B
Pregabalin[186,187,b]	NK	B
Primaquine[188,b]	NK	B
Promethazine[189,b]	NK	B
Propoxyphene[191,d,h]	NK	C
Propylthiouracil[190,d]	NK	C
Quinidine[192,c]	NK	B
Quinine[193,194,b,d]	20%	B
Ramipril[195,b]	2.2%	B
Rifampin[97,196,b]	NK	B
Rimantadine[197,c]	0.3–1%	B
Ritonavir[198,b]	2.6%	B
Ropinirole[199,b]	NK	B
Salicylates[200,c]	NK	B
Sertraline[80,c]	NK	C
Sildenafil[201,202,c,d]	<2%	C
Spectinomycin[203,b]	NK	C
Stavudine[141,142,d]	NK	C
Streptomycin[204,b,d]	4–75%	B
Sulfasalazine[205,c,d]	NK	B
Sulindac[82,c]	NK	C
Tacrolimus[206,d]	NK	C
Tadalafil[207,b]	NK	C
Temazepam[81,b]	1.2%	B
Telmisartan[23,b]	0.3–1%	B

Terazosin[208,b,c]	NK	B
Tetracaine[209,b]	NK	B
Tetracycline[156,157,b,c]	11–14%	B
Thalidomide[210,211,b]	NK	B
Thiabendazole[212,c]	NK	B
Thiethylperazine[213,c]	NK	B
Tiagabine[215,b]	NK	B
Ticlopidine[214,c]	NK	B
Tigecycline[216,c]	NK	B
Timolol[217,b]	NK	C
Tobramycin[218,b,d]	0–43%	B
Tolmetin[82,c,d]	<3%	C
Topiramate[219,220,b]	NK	C
Torsemide[96,105,106,c]	NK	B
Tramadol[221-224,b]	NK	A, B
Tranylcypromine[225,c]	NK	B
Trazodone[226,b]	NK	C
Valproic acid[227,228,c,d]	1–7%	B
Valsartan[229,b]	<1%	B
Vancomycin[230-232,d]	NK	B
Varenicline[233,b]	NK	C
Venlafaxine[80,c,i]	NK	C
Verapamil[165,b]	NK	C
Vinblastine[234,d]	NK	C
Vincristine[235,d]	NK	B
Vindesine[236,b,c]	<0.05%	A
Vinorelbine[237,c]	NK	A
Vitamin A[238,d,h]	NK	C
Zalcitabine[239,240,d]	NK	C
Zidovudine[141,142,d]	NK	B
Zolipidem[241,b]	NK	B
Zonisamide[242,b]	NK	B

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] Vertigo.

[c] Tinnitus.

[d] Ototoxicity.

[e] Of patients with end-stage kidney disease.

[f] Associated with cumulative dose and extended duration.

[g] Associated with accidental topical administration.

[h] In overdose.

[i] Associated with withdrawal symptoms.

EPIDEMIOLOGY

Drug-induced ototoxicity was first documented in the 17th century in association with quinine therapy, and salicylate ototoxicity was first reported in the 19th century.[251-253] The overall incidence of drug-induced auditory toxicity is not known, but there are known incidence rates with some individual drugs. The incidence of aminoglycoside-induced ototoxicity varies from 0% to >60% depending on the specific agent and the method of assessment.[9,114] The incidence of ototoxicity associated with chemotherapeutic agents is high, especially when dose-intense chemotherapy is administered.[46,148,149] The reported incidence of drug-induced auditory disorders associated with specific agents, where available, is included in Table 55-1.[1,8-242]

MECHANISMS

Drug-induced auditory disorders result from a number of mechanisms (**Table 55-2**[15,27,106,252,254-265]). Ototoxicity generally results from damage to the cochlea (leading to changes in hearing) or the vestibulum (leading to disorders of balance).[266,267] Architectural changes that can be caused by drugs closely resemble the damage caused by noise and aging.[4,268] The actual causes of the structural changes may be multifactorial.

Table 55-2 Mechanisms of Drug-Induced Ototoxicity[15,27,106 252,254-265]

Drug	Mechanism(s)

Aminoglycosides	Formation of reactive oxygen species
Aminoglycosides and chemotherapeutic agents	Decreased number of hair cells Loss of spiral ganglion
Chemotherapeutic agents	Changes in mitochondrial function Direct cell death
Chemotherapeutic agents and diuretics	Reduction in endocochlear potential
Diuretics	Disruption of endocochlear fluid homeostasis Disruption of endolymph homeostatis
Opioids, quinine, and salicylates	Decreased cochlear blood flow
Salicylates	Activation of NMDA receptors

NMDA = *N*-methyl-D-aspartate.

Aminoglycosides can cause the formation of reactive oxygen species that overwhelm the body's natural detoxification systems (glutathione, superoxide dismutase).[257,261,262] The physical changes in the inner ear induced by aminoglycosides include a decreased number of hair cells.[13,254,255] Loss of spiral ganglion—cells that conduct nerve impulses from the cochlea to the brain—has also been observed following aminoglycoside administration.[262,263]

Diuretics can cause temporary profound hearing loss through disruption of the homeostasis of the endocochlear fluid resulting in depression of the endocochlear potential.[252,255,256] The endocochlear fluid, endocochlear potential, and endolymph all are parts of the ear that allow sound to be converted into nerve impulses.[263] Although loop diuretics used alone generally cause only temporary hearing loss, they can potentiate the toxicity of other ototoxic agents, possibly by increasing their concentrations in the endolymph fluid covering hair cells resulting in much higher hair cell exposure.[252,255,263-265]

The primary mechanism of quinine and salicylate ototoxicity is thought to be decreased cochlear blood flow due to inhibition of prostaglandin synthesis.[252,255] This hearing loss is generally reversible and usually occurs only with high doses of the culprit agents.[256] Salicylate ototoxicity may also be caused by increasing labyrinthine pressure or vasoconstriction.[200] In addition, activation of *N*-methyl-D-aspartate (NMDA) receptors has been implicated in salicylate-induced tinnitus.[26] Similarly, it is thought that opioids reduce cochlear blood flow as a result of vasoconstriction leading to cochlear ischemia and hearing loss.[269]

Cancer chemotherapeutic agents damage the inner ear in a number ways. These drugs may cause direct cell death, disturb the homeostasis of the endolymph, or cause degeneration of hair cells.[254,255,270,271] In addition, cisplatin may impair function of the stria vascularis by reducing endocochlear potential. In the normal inner ear, the stria vascularis maintains the electrochemical gradient between the endolymph and the perilymph.[256] Cisplatin also reduces the number of spiral ganglion cells in areas of the cochlea that may otherwise appear normal.[262,270] Change in mitochondrial function has also been noted with cisplatin ototoxicity.[270]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Patient symptom reporting is generally the initiating event in the diagnosis of drug-induced ear disorders. Ototoxicity can result in cochleotoxicity, which leads to changes in hearing, and/or vestibulotoxicity, resulting in disorders of balance. Hearing and balance changes may be present simultaneously. Vestibular symptoms include vertigo, nausea, oscillopsia (problematic ocular fixation), dizziness, lightheadedness, and gait disturbance.[115,272] Common symptoms and symptoms of drug-induced ototoxicity are presented in **Table 55-3**.[9,115,252]

Table 55-3 Signs and Symptoms Associated with Drug-Induced Ototoxicity[9,115,252]

- Difficulty hearing television or conversation
- Disequilibrium
- Frank hearing loss
- Fullness in the ear
- Gait disturbance
- Lightheadedness
- Oscillopsia
- Tinnitus

Table 55-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Ototoxicity[274-276]

Hearing Loss (sensorineural)

- Acoustic neuroma
- Autoimune disease
- Barotrauma
- Cerebrovascular ischemia/stroke
- Meniere disease
- Meningioma
- Meningitis
- Multiple sclerosis
- Noise exposure
- Ototoxic medications

- Penetrating trauma
- Presbycusis
- Viral infections

Tinnitus

- Cerebrovascular ischemia/stroke
- Chronic renal failure
- Diabetes
- Fibrous dysplasia
- Hypercholesterolemia
- Hypertension
- Infection
- Medications
- Osteogensis imperfecta
- Otosclerosis
- Paget disease
- Rheumatoid arthritis
- Sarcoid
- Sickle cell anemia
- Stroke
- Systemic lupus erythematos
- Thyroid disease
- Tumors

Vertigo

- Acoustic neuroma
- Benign paroxysmal positional vertigo
- Cogan syndrome
- Herpes zoster oticus
- Labyrinthine concussion
- Medications
- Meniere disease
- Otitis media
- Perilymphatic fistula
- Recurrent vestibulopathy
- Semicircular canal dehiscensce syndrome
- Vestibular neuritis

Diagnosis of ototoxicity can be challenging due to the variability in symptom severity and inconsistent presentation among patients. The primary reason for delayed diagnosis is the propensity for hearing loss to develop initially at frequencies above those used in daily conversation.[273] Initial symptoms may include perceived fullness in the ear, tinnitus, difficulty hearing the television or radio, or difficulty talking on the telephone.[115] **Table 55-4** lists the conditions that should be considered in the differential diagnosis of drug-induced ototoxicity.[274,275]

Baseline audiometric testing for all patients receiving a drug with a potential to cause ototoxicity has been recommended. This is not always done, however, due to the large number of drugs known to cause ototoxicity, the cost of testing, and inconsistent practices or prescreening.[273,277] At a minimum, efforts should be made to do baseline audiometric testing and testing during treatment for those patients receiving medications with the highest risk of ototoxicity. In addition, audiometric monitoring of selected high-risk patient populations (e.g., children who are still developing language skills) may allow detection of ototoxicity at an early stage so that disability can be prevented.[278]

There are three main approaches currently used for monitoring: ototoxicity basic audiologic assessment, high frequency audiometry, and otoacoustic emission.[279] The latter two methods are becoming more widely used to evaluate ototoxicity because they are less resource-intense and are easier for patients even when critically ill.[279] However, none of these assessment approaches is appropriate for all patients.

RISK FACTORS

Risk factors for drug-induced ototoxicity are listed in **Table 55-5**.[16,45-51,61,77,109,114,115,117,204,252,256,280-287] High drug doses (e.g., with NSAIDs, diuretics) and, in some cases, cumulative doses (e.g., with aminoglycoside antibiotics, oncologic agents) are occasionally predictors of ototoxicity.[38] Rapid administration of intravenous (IV) loop diuretics is a risk factor for ototoxicity.[267]

Table 55-5 Risk Factors for Drug-Induced Ototoxicity[16,45-51,61,77,109,114,115,117,204,252,256,280-287]

- Age
- Bacteremia
- Concomitant or prior exposure to ototoxic drugs
- Cranial radiation
- Cumulative dose
- Decreased serum albumin concentration
- Decreased serum hemoglobin concentration, hematocrit, and red blood cell count
- Diet (magnesium and zinc deficiency, low protein)
- Duration of therapy >14 days
- Electrolyte imbalances
- Elevated serum iron concentration
- Elevated temperature
- Genetic mutation in mitochondrial RNA
- Hepatic dysfunction
- High daily dose
- Hypovolemia
- Meningitis
- Neonatal intensive care unit
- Noise exposure
- Pre-existing hearing problems
- Renal dysfunction

RNA = ribonucleic acid.

Familial groupings of individuals at increased risk for aminoglycoside ototoxicity have been reported.[205] Several point mutations (A1555G, T deletion at 961) in the mitochondrial 12S rRNA of selected families was confirmed to predispose members to both familial deafness and aminoglycoside-induced ototoxicity. At least one of the mutations facilitates binding of the aminoglycoside to the mitochondrial RNA.[283] Studies indicate that development of ototoxicity is due to changed mitochondrial protein synthesis.[204,267,283]

Factors reported to increase the risk of aminoglycoside ototoxicity include total dose administered, duration of administration >14 days, dehydration, hypotension, metabolic acidosis, hypokalemia, hypomagnesemia, renal dysfunction, hepatic dysfunction, and concomitant administration of other ototoxic agents.[27,106,107,120,158,267,288] Gentamicin and tobramycin peak concentrations >12 mg/L and trough concentrations >2 mg/L, have been reported to increase the risk of ototoxicity.[288] Similarly, peak serum amikacin concentrations >35 mg/L and trough concentrations >10 mg/L have been reported to increase the risk of ototoxicity.[288]

Vancomycin ototoxicity does not occur in animal models, and some studies indicate that it is related to concomitant use of other ototoxic medications.[244,245] However, evidence from the 1950s suggested that peak serum vancomycin concentrations >80 mg/L were associated with hearing loss.[244] There is also a case report of a neonate who received an accidental overdose of vancomycin (serum concentrations >100 mg/L for 4 days) who subsequently had no evidence of hearing loss.[285] Reversible tinnitus has been reported in patients with serum vancomycin concentrations >40 mg/L.[284,288]

Animal research and limited human studies suggest low-protein diets and lower serum albumin concentrations increase the risk for cisplatin-induced ototoxicity.[280] In a small group of patients who participated in audiometric testing prior to cisplatin therapy, those with poorer health status as indicated by lower serum albumin concentration and anemia experienced a higher rate of hearing loss than those in better health.[289] Low serum albumin concentrations may lead to higher unbound cisplatin concentrations increasing the risk of ototoxicity; however, apoptosis of cochlear cells and avid cisplatin tissue binding are more problematic than decreased levels of albumin.[290] Decreased blood flow and oxygen availability secondary to anemia may play a role in developing hearing loss due to reduced metabolism.[289]

Elevated blood concentrations of metals such as iron can potentiate the formation of the reactive oxygen species.[291,292] Iron accumulation in transfusion-dependent patients has been associated with end organ damage in some patient populations, and deferoxamine is frequently used to decrease the iron burden.

Sensorineural hearing loss has been reported in 3.8–57% of these patients.[293] Some investigators attribute the hearing deficit to iron overload, while others ascribe it to deferoxamine. Chiodo and colleagues found no association between risk of ototoxicity and serum ferritin and hemoglobin concentrations.[77,79] One study found an association between higher doses of deferoxamine given less frequently compared to lower doses administered daily.[77] Iron may also play a role in ototoxicity induced by aminoglycosides by forming complexes with the drugs. These complexes serve as precursors to free radical formation.[292] The risk of ototoxicity associated with furosemide is increased with prolonged duration of therapy.[294]

MORBIDITY AND MORTALITY

The exact incidence of ototoxicity has not been quantified, but it is approximated that millions of patients are exposed to ototoxic medications annually. Hearing loss and, sometimes, tinnitus due to ototoxicity can cause permanent disability.[295] In children, hearing difficulties impact social, emotional, and cognitive development.[36] Children with hearing problems have delayed language development and reading skills. Hearing loss also causes social and emotional challenges for adults including decreased quality of life due to struggles with communicating, cognitive decline, social isolation, and development of depression.[296]

Table 55-6 Approaches to Help Prevent Drug-Induced Ototoxicity[288-308]

Currently Available

- Avoid rapid intravenous infusions
- Close monitoring
- Limiting therapy duration
- Limiting total dose
- Risk assessment

Investigational

- α-MSH
- α-tocopherol
- Amifostine
- Ethacrynic acid
- Glial derived neurotrophic factor
- Glutathione
- Intensity-modulated radiation therapy
- Iron chelators

- Melatonin
- *N*-acetylcysteine
- Neurotrophic peptide ORG 2766
- Salicylates
- Sodium thiosulfate
- Superoxide dismutase

MSH = melanocyte-stimulating hormone.

PREVENTION

Prevention of drug-induced ototoxicity requires appropriate risk assessment and close monitoring.[297] Methods of prevention are listed in **Table 55-6**.[288-308] Administration of numerous chemicals to provide protection from ototoxicity and enhance recovery of hearing are under investigation.[277,289] Included in this group are drugs commonly used for other indications.[271,289,290,296,304,305,309-314] Acetylcysteine protects auditory neurons and hair cells from cisplatin ototoxicity in vitro.[305] Concomitant administration of the nutritional supplement α-tocopherol with gentamicin has delayed progression of hearing loss and preserved vestibular function in animals.[301] Other promising experimental agents include diethyldithiocarbamate, glutathione, and methionine.[289,296] No drugs are currently U.S. Food and Drug Administration (FDA)–approved specifically for prevention of drug-induced ototoxicity.

Judicious administration of aminoglycosides to only those patients with serious infections and limiting the duration of exposure can help prevent permanent hearing loss. Unfortunately, in the current era of more widespread antimicrobial resistance, the use of aminoglycosides in combination with other antibiotics is sometimes required in the treatment of serious infections such as *Pseudomonas aeruginosa*.

Prevention of cancer chemotherapy-induced ototoxicity is complicated. A primary concern with the use of preventive measures is the possibility that the anti-tumor activity of the antineoplastic agent could be compromised. Several strategies for retaining the cytotoxic properties of cancer chemotherapy agents while reducing the incidence of ototoxicity are in the early stages of testing. These include compartmentalization of medication, timed dosing, and localized cranial radiation.[296,297,307]

There are some data supporting the use of sodium thiosulfate to protect children and adults from ototoxicity during carboplatin treatment. Sodium thiosulfate provided protection from ototoxicity when administered in a dose of at least 16 g/m^2 4 hours after carboplatin treatment.[315]

Salicylates and ethacrynic acid—drugs that may themselves cause temporary hearing loss—have actually shown promise for protecting from drug-induced ototoxicity caused by other agents when administration is timed appropriately.

Animal data revealed salicylates can chelate iron and serve as an antioxidant against gentamicin-induced hearing loss without affecting antibiotic efficacy.[299] Administration of ethacrynic acid when serum gentamicin concentrations are highest in the cochlear fluid facilitates excretion, leading to loss of fewer outer hair cells and lower compound action potential thresholds.[304]

MANAGEMENT

Treatment of reversible ototoxicity as with salicylate- or furosemide-induced tinnitus involves simply discontinuing therapy with the offending agent.[252] Generally, tinnitus resolves within several days.[29] When offending medications cannot be discontinued and/or damage is permanent, specific treatment measures are indicated. For patients who experience permanent drug-induced hearing loss, options include hearing aids and cochlear implants.[257]

Several options for the treatment of tinnitus have been explored, although evidence of the effectiveness of drugs in the treatment of this condition is largely anecdotal. Agents that are well-known causes of tinnitus have also been used in its treatment (e.g., benzodiazepines, furosemide, lidocaine, prednisone, metformin), albeit with limited success.[109,308] Anesthetics, antidepressants, anticonvulsants, anxiolytics, antihistamines, diuretics, and antispasmodics have all been studied but had little to no benefit and were associated with adverse effects.[304,308-314] There have been several antioxidants that have been shown some efficacy of alleviating ototoxicity; however, to date there are no human trials with these medications.[316-320]

The use of frequency masking devices and patient counseling on ways to live with tinnitus remain the mainstays of treatment for this disorder.[304,314] Frequency masking devices produce a sound that masks the tinnitus sound patients hear.[311] The device emits a frequency that is similar in pitch to the tinnitus sound effectively blocking out that sound.[311] These devices can be incorporated into hearing aids or used separately, and patients who utilize them report good success in masking their tinnitus.[311]

There is continuing research on treatment options for vestibular dysfunction. Antihistamines such as diphenhydramine, meclizine, and promethazine have been shown to provide some benefit for patients suffering from vestibular dysfunction.[321] Other treatment options include trimethadione and scopolamine patches.[321] Vestibular rehabilitation exercises are often required to help patients learn adaptation to residual reflexes or substitution of ocular and proprioception cues.[121]

INFORMATION FOR PATIENTS

Patients who are taking drugs known to cause auditory disorders should be instructed to consult their healthcare provider should they notice a change in hearing acuity or unusual sounds in the ears which might include ringing, buzzing, clicking, hissing, or roaring.[322] Patients should be instructed to avoid concomitant use of drugs known to cause ototoxicity for the duration of their treatment with a potentially ototoxic medication.[323,324] It would also be reasonable for healthcare providers to review medication lists to identify any other ototoxic medications and evaluate their continued need. Information about the warning signs of ototoxicity such as dizziness, ringing in the ears, worsening of tinnitus, unexplained ear pressure, and any abnormal hearing changes should be communicated to the patient when they start medications known to cause ototoxicity.[324] Patients should also be instructed to keep hydrated, avoid caffeine, and avoid loud music or noises while taking ototoxic medications.[324]

CHAPTER 56

Oral Manifestations of Systemically Administered Drugs

Ashley H. Meredith

Many commonly prescribed drugs have associated dental and oral manifestations that are often nonspecific and can vary in significance. Undesirable effects can mimic other disease processes, as is often the case with erythema multiforme, or may be very characteristic of a particular agent, such as gingival hyperplasia secondary to the anticonvulsant phenytoin. Several systemic drugs and medication classes have been implicated in causing clinically significant oral manifestations. The drug-induced diseases covered in this chapter include color changes of the oral mucosa and teeth, taste disorders, gingival hyperplasia, oral erythema multiforme, oral lichenoid drug reactions, and osteonecrosis of the jaw.

COLOR CHANGES OF THE ORAL MUCOSA AND TEETH

Color changes within the oral cavity may be classified as extrinsic (i.e., superficial discoloration) or intrinsic (i.e., within the mucosa or tooth structure).[1] Extrinsic discoloration rarely leads to clinically significant disease.

CAUSATIVE AGENTS

Any surface within the oral cavity is subject to discoloration due to medications. The most commonly impacted areas include the teeth and palate. Substances reported to cause color changes of the teeth include coffee, tobacco, tetracycline, minocycline, and fluoride.[2] Color changes of the oral mucosa have been associated with oral contraceptives, minocycline, chloroquine, phenytoin, and amiodarone.[3-9] In patients with HIV disease, diffuse or macular pigmentation has been reported within the oral mucosa with clofazimine, zidovudine, or ketoconazole treatment.[18] Drugs reported to cause color changes of the oral mucosa and teeth are listed in **Table 56-1**.[3-36]

Table 56-1 Agents Implicated in Drug-Induced Color Changes of the Oral Mucosa and Teeth[3-36]

Drug	Incidence	Level of Evidence[a]
5-fluorouracil[10-12]	<1%	B
Amiodarone[9-11,13]	<1%	B
Bismuth[10,14]	NK	B
Bleomycin[10-13]	8–40%	B
Busulfan[10,12-14]	<1%	B
Carotene[10-12]	NK	C
Chlorhexidine[11,12,14]	56%	B
Chloroquine[7,10,13-15]	<1%	B
Chlorpromazine[10,13,17]	<1%	C
Clofazimine[10-14,18]	75–100%	C
Copper[14]	NK	C
Cyclophosphamide[10-14,19-21]	NK	B
Docetaxel[19-21]	NK	B
Doxorubicin[10,12-14,19-21]	NK	B
Enalapril[14]	<1%	C
	NK	C

Fosinopril[14]		
Gold[10,22]	NK	B
Heroin[11-14]	NK	C
Hydroxychloroquine[10,13,16,23]	<1%	B
Hydroxyurea[13]	<1%	C
Imatinib[24,25]	NK	B
Iron[14]	NK	C
Ketoconazole[11-13]	NK	B
Lansoprazole[25]	<1%	C
Lead[10,14]	NK	C
Lisinopril[14]	NK	C
Manganese[14]	NK	C
Methyldopa[14]	<1%	C
Minocycline[5,6,10-12,14,27-32]	10–20%	A
Nicotine[11,12]	NK	B
Oral contraceptives[3,4,10-14]	NK	B
Pentamidine[14]	NK	C
Perindopril[14]	NK	C
Phenytoin[8,14]	NK	B
Premarin[11,12,33]	<1%	C
Propafenone[14]	NK	C
Quinacrine[10,13,14]	4–37%	B
Quinapril[14]	NK	C
Ramipril[14]	NK	C
Silver[14]	NK	C
Tacrolimus[13,34]	NK	C
Terbinafine[14]	NK	C
Tetracycline[10-13,27,29]	3–4%	A
Thallium[14]	NK	C
Tin[14]	NK	C
Trandolapril[14]	NK	C
Zidovudine[11-14,18,35,36]	NK	B

Zopiclone[14]	NK	C

NK = not known.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

EPIDEMIOLOGY

The overall incidence of drug-induced color changes of the oral mucosa and teeth is unknown. The incidence of minocycline-induced hyperpigmentation increases with higher doses and longer durations of exposure. It has been reported to occur in 10% of patients after 1 year and increases to 20% after 4 years of treatment with minocycline 100–200 mg per day.[31]

MECHANISMS

Color changes of the teeth can be caused by physical contact with a substance that causes external staining (e.g., coffee or tobacco) or may be due to changes that occur during tooth formation, as is the case with the tetracyclines.[2] **Table 56-2** describes mechanisms of drug-induced color changes of the oral mucosa and teeth.[25,37,38] The proposed mechanism by which antimalarial agents induce color changes involves deposition of melanin or iron within the mucosal tissues.[1] Minocycline- and tetracycline-related color changes of the teeth are a result of a direct chelation with calcium and incorporation into hydroxyapatite as a stable organophosphate complex during tooth formation.[1,39] Additional mechanisms for drug-induced color changes of the oral mucosa and teeth include deposition of pigmented metabolic drug products within the mucosal tissues, increased melanin production and deposition, and deposition of exogenous materials.[7,16,37,40]

Table 56-2 Mechanisms of Drug-Induced Color Changes of the Oral Mucosa and Teeth[25,37,38]

Drug	Mechanism(s)
Amiodarone	• Increased lipofuscin production[37]
Antimalarials	• Increased melanin production[37]
Clofazamine	• Chelated medication metabolite(s)[37]
Heavy metals (i.e., arsenic, bismuth, lead, mercury, silver, gold)	• Peripheral metal accumulation in the oral mucosa[38]

Hormones	- Increased melanin production[37]
Imatinib	- Chelated medication metabolite[25]
Tetracyclines	- Increased melanin production[37] - Formation of iron complex[37] - Stained bone[37]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The signs and symptoms of drug-induced color changes of the oral mucosa and teeth are somewhat variable (**Table 56-3**).[10] Pigmentation can range from light brown to black, with brown lesions typically related to superficial pigmentation and black/gray lesions related to deeper pigment location.[13,40] More intense colors are found in patients who smoke.[41] Any area within the oral mucosa may be impacted, with the buccal and gingival mucosa and hard palate most commonly affected.[31,40] Areas of hyperpigmentation may be diffuse or multifocal.[37] Patients presenting with tetracycline-related tooth discoloration typically have a brownish color on the front teeth and a yellow color on the back teeth. This difference is due to daily light exposure, which is more intense in the front portion of the mouth as opposed to the back.

Table 56-3 Signs and Symptoms of Drug-Induced Oral Manifestations of Systemic Drugs

Signs	Symptoms
COLOR CHANGES OF THE ORAL MUCOSA AND TEETH	
Diffuse hyperpigmented lesion(s) of various colors (i.e., blue-gray, brown, red) Histologic exam[10]: - Increased melanin in all epidermal layers - Pigment granules within dermis	Generally asymptomatic
DRUG-INDUCED TASTE DISORDERS	
No objective signs present	Absence of normal taste sensations (i.e., excessively sweet, bitter, salty or metallic tastes)
DRUG-INDUCED GINGIVAL HYPERPLASIA[154]	
Localized or generalized gingival enlargement Firm nodular enlargement Lobulated gingival appearance	Bleeding Pain

Noninflamed, firm, and fibrous gingiva Edematous, erythematous, and bleeding gingiva	Impaired oral hygiene[125] Difficulty chewing[125] Speech interference[125]
DRUG-INDUCED ORAL ERYTHEMA MULTIFORME[172,189,190]	
Diffuse macules that blister and form ulcers Intraoral lesions Swollen, cracked, bleeding, and crusted lips Targetoid lesion (central necrotic area)	Fever Pain
DRUG-INDUCED ORAL LICHENOID REACTIONS[230]	
Oral ulcerations with Wickham's striae[2,74] Swollen, red, and ulcerated lesions[229] White reticular striae or plaques[229]	Pain Roughness on lining of the mouth Sensitivity to hot or spicy foods Slow onset of ulcers
DRUG-INDUCED OSTEONECROSIS OF THE JAW[241]	
Cutaneous fistula Exposed bone Mobile teeth Mucosal fistula	Delayed tissue healing[266,267] Pain

When a patient presents with complaints of color changes within the oral cavity, multiple diagnoses must be considered in addition to drug-induced disease. **Table 56-4** lists conditions to consider in the differential diagnosis of drug-induced color changes of the oral mucosa and teeth.[7,13] The differential diagnosis should include conditions such as Addison disease, vitamin B_{12} deficiency, and melanoma. Addison disease and vitamin B_{12} deficiency can be ruled out with blood tests.[7] If the index of suspicion for melanoma is high, this diagnosis can be investigated via incisional biopsy of the hyperpigmented area. Pigmentation of the oral cavity may be due to exogenous causes such as tattoo pigment, pencil lead, or amalgam, a common product used in dental restorations. Amalgam use as part of dental restoration can result in the generation of corrosive products, such as silver sulfide, resulting in grayish-black discoloration. Pigmented lesions often require a biopsy to establish a definitive diagnosis.[13]

Table 56-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Oral Manifestations of Systemic Drugs

Drug-induced color changes of the oral mucosa and teeth

- Acquired melanocytic nevi[13]
- Embedded foreign material (i.e., tattoo pigment, amalgam dental restoration material, pencil lead)[13]

- Endogenous sources (i.e., hemoglobin, bilirubin)[13]
- Physiological conditions (i.e., Addison disease, Peutz–Jeghers syndrome, Laugier–Hunziker syndrome)[13]
- Postinflammatory pigmentation[13]
- Primary and metastatic melanoma[13]
- Tobacco use[13]
- Vitamin B_{12} deficiency[7]

Drug-induced taste disorders[43]

- Gingivitis
- Lead or copper poisoning
- Recent dental procedures
- Thrush
- Upper respiratory tract infection
- Zinc deficiency

Drug-induced gingival hyperplasia[156]

- Gingivitis
- Hormonal conditions (i.e., pregnancy, hypothyroidism)
- Leukemia (i.e., acute monocytic, lymphocytic, myelocytic)
- Nutritional conditions (i.e., vitamin C deficiency)

Drug-induced oral erythema multiforme[187]

- Bullous pemphigoid
- Cutaneous small-vessel vasculitis
- Fixed drug eruptions
- Paraneoplastic pemphigus
- Polymorphous light eruption
- Stevens–Johnson syndrome
- Sweet syndrome
- Rowell syndrome
- Urticaria

Drug-induced oral lichenoid reactions[201,222,231]

- Candidiasis
- Chronic ulcerative stomatitis
- Desquamative gingivitis
- Graft versus host disease following allogenic bone marrow or stem cell transplant
- Lupus erythematosis
- Lichenoid dysplasia
- Mucous membrane pemphigoid
- Oral hairy leukoplakia
- Oral lichen planus
- Pemphigus vulgaris
- Poor oral hygiene
- Proliferative verrucous leukoplakia
- Squamous cell carcinoma

Drug-induced osteonecrosis of the jaw[249]

- Fungal infection
- Osteoradionecrosis

RISK FACTORS

Few specific risk factors for drug-induced color changes of the oral mucosa and teeth exist (**Table 56-5**). Trauma, hormonal changes, medication, and radiation can cause increased melanin production and lead to an increased incidence of oral pigmentation.[42] The administration of medications known to induce color changes should be limited if patients are known to have increased melanin production. Given the mechanism by which the tetracyclines cause color changes of the teeth, age and developmental stage should be considered as risk factors for this adverse effect.

MORBIDITY AND MORTALITY

No cases of morbidity or mortality associated with drug-induced color changes of the mucosa or teeth have been reported. The clinical consequences are mostly cosmetic, but the impact that the cosmetic changes may have on a patient's quality of life must be considered.

PREVENTION

The most effective prevention strategy for drug-induced color changes of the oral mucosa and teeth is limiting patients' exposure (dose and duration) to drugs known to carry this risk. Drugs of the tetracycline class should be avoided (to the extent medically possible) in women during the last half of pregnancy and in all children up to the age of 8 years.

Table 56-5 Risk Factors for Drug-Induced Oral Manifestations of Systemic Drugs

Color changes of the oral mucosa and teeth

- Age of the patient
- Chronic inflammation
- Duration of medication exposure
- Early stages of tooth development (tetracycline-induced)
- Hormonal changes
- Increased melanin production
- Trauma
- Trimester of pregnancy

Drug-induced taste disorders

- Concomitant chemotherapy[89]
- Female sex[61]

- Lower body-mass index[71]
- Older age[84,90-92]
- Radiation
- Vitamin D deficiency[93]
- Zinc deficiency[89]

Drug-induced gingival hyperplasia[126]

- Duration of treatment
- Male sex
- Plaque-induced inflammation
- Poor oral hygiene
- Young age

Drug-induced oral erythema multiforme

- Human leukocyte antigen (HLA) types: HLA-DQ3, HLA-B15(B62), HLA-B35, HLA-A33, HLA-DR53, HLA-DQB1*0301[179]
- Male sex[195]
- Younger age[195]

Drug-induced oral lichenoid reactions

- Female sex[233]
- Medication contains a thiol chemical group[208,228]

Drug-induced osteonecrosis of the jaw

- Cancer that has metastasized to the bone[266]
- Combination treatment with bisphosphonate and bevacizumab or sunitinib[251]
- Dental extractions[266]
- Intravenous bisphosphonate administration[249]
- Length of exposure to bisphosphonates (>6 months)[240,257]
- Multiple myeloma[266]
- Overall poor oral health[266]
- Surgical bone manipulation[266]
- Presence of oral infections[266]
- Trauma from dentures[266]

MANAGEMENT

Drug-induced color changes of the oral mucosa are benign, and no treatment is required once diagnosed. The pigmentation should resolve within a few months of medication discontinuation.[37] Tetracycline-induced pigmentation is irreversible, but the intensity may decrease over the years following discontinuation.[31]

INFORMATION FOR PATIENTS

When patients present with medication-induced color changes of the oral mucosa and teeth, healthcare providers should reassure the patient that it is a completely benign condition and is not commonly associated with long-term effects (unless due to tetracyclines).

TASTE DISORDERS

Three primary taste disorders exist: hypogeusia, ageusia, and dysgeusia. Hypogeusia is a decreased sensitivity to tastes, and ageusia is a total loss of taste perception. Dysgeusia is the distortion or misinterpretation of a taste while eating (i.e., tasting sour instead of sweet) or taste confusion.[43] Patients with dysgeusia may have an exaggerated sense of sweet, bitter, salty, or metallic tastes.[44,45]

CAUSATIVE AGENTS

Many drugs have been associated with disorders of taste including clarithromycin, terbinafine, furosemide, boceprevir, and telaprevir (**Table 56-6**).[14,43,46-72]

EPIDEMIOLOGY

Hypogeusia, ageusia, and dysgeusia are often grouped together and labeled simply as "taste changes" or "taste disorders." Medication-induced taste changes have been reported to account for 0.4% of reported adverse drug events, and this adverse event occurs more often in elderly patients, with a reported incidence of up to 33%.[46,47] Medications are thought to be the cause for up to 25% of all reported taste disturbances.[73] Cardiovascular agents carry a risk of causing taste disorders of approximately 2%.[74] Taste disorders have been reported in approximately 56% of cancer patients receiving chemotherapy alone, 66% of patients receiving radiation alone, and 76% in patients receiving both chemotherapy and radiation.[75,76]

Table 56-6 Agents Implicated in Drug-Induced Taste Disorders[14,43,46-72]

Drug	Incidence	Level of Evidence[a]
5-fluorouracil[14,43,47-49,52]	NK	B

Acetazolamide[14,43,47-49]	NK	B
Allopurinol[14,43,47-49]	NK	B
Alprazolam[53]	NK	C
Amlodipine[53]	<0.1%	C
Amoxicillin–clavulanic acid[46]	NK	B
Amphetamines[43,47-49]	NK	B
Amphotericin B[14,43,47-49]	NK	B
Aspirin[14,47-49]	NK	B
Atorvastatin[14,47]	NK	C
Azathioprine[14,54]	NK	C
Azithromycin[46]	<1%	B
Beceprovir[50]	18–43%	C
β-lactam antibiotics[43,47-49]	NK	B
Botulinim toxin A[47-49]	NK	C
Bupivacaine[47-49]	NK	C
Captopril[14,43,47-49,55]	2–4%	B
Carbamazepine[43,47-49]	NK	B
Carboplatin[43,52]	1%	C
Ceftriaxone[47-49]	<1%	C
Chlorhexidine[43,56]	NK	C
Cisplatin[14,43,47-49,52]	NK	B
Clarithromycin[14,46-49]	0.4–18.9%	B
Crizotinib[57-59]	26%	A
Cyclophosphamide[52]	NK	C
Diltiazem[14,43]	< %	C
Dipyridamole[14,43,47-49]	NK	B
Disulfiram[47-49]	NK	C
Docetaxel[60]	NK	C
Doxorubicin[52]	NK	C
EDTA[14,43]	NK	C
Enalapril[14,43]	0.5–2.9%	C
Eprosartan[47-49]	NK	C

Ergocalciferol[47-49]	NK	C
Eszopiclone[61,62]	26–62%	A
Ethambutol[14,43,47-49]	NK	B
Ethionamide[14,43]	NK	C
Ferrous sulfate[47-49]	1.1%	C
Fluoxetine[47-49]	NK	C
Flurazepam[43,47-49]	NK	C
Furosemide[47-49]	NK	C
Interferon α[43]	1%	C
Isosorbide dinitrate[14,43]	NK	C
Isotretinoin[43,63]	NK	C
Lamotrigine[47-49]	NK	C
Levamisole[43]	7%	C
Levodopa[14,43,47-49]	>3%	B
Levofloxacin[46]	8–10%	B
Lisinopril[14,43,47,55]	NK	B
Lithium[14,43,47-49,64]	NK	B
Losartan[14,43,47,65]	NK	B
Metformin[47-49]	NK	C
Methocarbamol[47-49]	NK	C
Methyldopa[47-49]	NK	C
Metolazone[47-49]	NK	C
Metronidazole[14,43,47-49,66]	2–9%	B
Moxifloxacin[46]	0.1≤1%	B
Nifedipine[14,43,47-49,67]	NK	B
Nitroglycerin[14,43]	NK	C
Olanzapine[53]	NK	C
Paclitaxel[60]	NK	C
Penicillamine[14,43,47-49]	12%	B
Pentamidine[14,43,47-49,68]	NK	B
Pergolide[14,43]	1.6%	C
	NK	C

Pravastatin[47]		
Procainamide[47-49]	3–4%	C
Procaine penicillin G[14,43,47-49]	NK	B
Propafenone[14,43,47-49]	>5%	B
Propylthiouracil[14,43]	NK	C
Protease inhibitors[46,69]	NK	B
Ramipril[14]	NK	C
Risperidone[47-49,70]	NK	A
Selegiline[14,43]	1≥3%	C
Simvastatin[47]	NK	C
Sulfasalazine[14,43,47-49]	NK	B
Sulfisoxazole[47-49]	NK	C
Sulindac[47-49]	NK	C
Sumatriptan[47-49]	13.5–24.5%	C
Sunitinib[46]	21–47%	B
Telaprevir[51]	27%	B
Terbinafine[14,43,46-49,71]	2.8–9%	B
Tetracycline[14,43,47-49,72]	NK	B
Vitamin D[47-49]	NK	C
Zopiclone[14,47-49]	15–30%	B

EDTA = ethylenediaminetetraacetic acid, NK = not known.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

MECHANISMS

Multiple mechanisms exist that may explain how medications cause taste disturbances (**Table 56-7**).[43] Taste disorders may be secondary to hyposalivation as a result of damage to the salivary glands, change in chemical composition of the saliva, or via other mechanisms such as drug-receptor inhibition, alteration of neurotransmitter function, neuron action potential disruption, or dysfunctional sensory modulation in the brain.[46,55,77,78] Chemotherapy may cause taste disturbances due to higher rates of cell turnover and taste bud cell death.[76,79] Taste disturbances related to radiation are a result of damage to the nerves responsible for processing taste function, anatomic changes, and a direct decrease in taste bud density due to cytotoxic and antiproliferative effects.[76,79-83]

Table 56-7 Mechanisms of Drug-Induced Taste Disorders

Drug	Mechanism(s)[43]
Acetazolamide Tetracycline	• Dysfunction of taste bud or neuron
Allopurinol Dipyridamole Lithium	• Alteration of secondary messenger systems that leads to misinterpretation of tastes
Amphetamines	• Decreased taste threshold
Captopril Enalapril Lisinopril	• Excess bradykinin accumulation • Zinc deficiency
β-lactam antibiotics EDTA Penicillamine Propylthiouracil	• Zinc chelation
5-fluorouracil	• Mucosal toxicity
Diltiazem Nifedipine	• Decreased calcium-mediated neurotransmission

EDTA = ethylenediaminetetraacetic acid.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Taste disorders often present with patients complaining of strange tastes, changes to the taste of food, or lack of taste (Table 56-3). Symptoms may begin suddenly or have a gradual onset. When related to radiation therapy, taste disorders peak 3–4 weeks after the start of treatment.[84]

Differential diagnoses for taste disorders include upper respiratory tract infections, dental causes, or structural changes (Table 56-4).[43,85,86] Tests to rule out nondrug causes may include computed tomography and magnetic resonance imaging to look for structural changes that may be contributing to the taste disorder and to assess neurologic or intracranial causes.[87] Simple taste testing based on exposure to substances known to produce certain tastes, such as salty or sweet, can be completed to confirm the diagnosis of dysgeusia and other taste disorders.[88]

RISK FACTORS

Many nonspecific risk factors exist that may predispose patients to taste disorders (Table 56-5).[61,71,84,90-93] Some data suggest women may be more sensitive to taste disturbances related to medications.[61] Lower body mass index is thought to increase the risk from lipophilic drugs, such as terbinafine.[71] Older age is associated with an increased risk due to a decreased quality of taste buds and higher number of daily medications to treat chronic medical conditions.[90-92] Zinc and vitamin D deficiencies have been linked to taste disturbances, particularly when patients are receiving chemotherapy.[89,93] Higher doses of radiation may be associated with more severe symptoms.[84]

MORBIDITY AND MORTALITY

Overall, taste disturbances can lead to decreased appetite, poor food choices, and decreased intake contributing to malnutrition, worsening of medical conditions impacted by dietary choices, and impaired immune function.[49] Taste disturbances do not directly cause morbidity and mortality; however, it has been estimated that up to 20% of deaths in cancer patients may be attributed to malnourishment resulting from decreased enjoyment of food.[94] Studies in cancer patients yield conflicting results concerning the impact taste disturbances have on quality of life. Some studies have found that approximately 50% of patients list taste disturbances in their top three treatment-related complaints, although other studies refute those reports.[84]

PREVENTION

Limiting drug exposure (dose and duration of treatment) is the most effective means for preventing all of the oral manifestations of systemically administered drugs. Unfortunately, no specific methods for the prevention of taste disturbances have been identified.

MANAGEMENT

Taste disturbances are best treated with removal of the offending agent.[14] Resolution of symptoms may take months due to accumulated metabolites. Small trials have reported improvement in symptoms with the use of alpha lipoic acid (200 mg given orally 3 times daily) or zinc supplementation (50 mg given orally 3 times daily), particularly if zinc deficiency is identified.[95-97] For chemotherapy patients with a documented decreased 25-hydroxyvitamin D level, daily supplementation with 2,000 units of vitamin D_3 (cholecalciferol) orally was found to be successful in reducing treatment-related taste disorders.[93] Clonazapem has been found to be effective for some types of dysgeusia due to its action on gamma-aminobutyric acid receptors.[98]

If taste disturbances persist following removal of the offending agent, masking techniques such as the use of breath mints or sugarless chewing gum may be utilized. These approaches may have limited efficacy, however, due to loss of flavor from the underlying taste disturbance. Lozenges containing the local anesthetic dyclonine (e.g., Sucrets) may provide temporary relief.[44] A case report found improvement in dysgeusia when patients held an ice cube in the mouth before meals.[99] Patients may also see improvement with the use of plastic utensils, eating food cold, and, in severe cases, use of an oral suspension composed of lidocaine, aluminum-magnesium hydroxide, and diphenhydramine.[60]

INFORMATION FOR PATIENTS

Patients with drug-induced disturbances of taste should understand that the disorder could cause them to either eat too much and gain weight or eat too little and lose weight. Flavor enhancement can increase food enjoyment, even in the presence of taste disturbances; however, if salt or sugar is used, it may have an impact on chronic conditions such as hypertension or diabetes. Techniques such as marinating meats before cooking, using low-calorie sweeteners for sweetness, and using lemon juice for sourness can sometimes improve taste and help increase caloric intake. It is important for patients to make a conscious effort to maintain proper nutrition, utilizing supplements and dietary guidelines.[100-103]

GINGIVAL HYPERPLASIA

Gingival hyperplasia often begins as a painless enlargement that is usually generalized throughout the mouth. There is an accumulation of extracellular components within the gingival connective tissue associated with various degrees of chronic inflammation.

CAUSATIVE AGENTS

There is a definitive link between medications and gingival hyperplasia. Multiple medications have been reported to cause gingival hyperplasia, including cyclosporine, sodium valproate, nifedipine, diltiazem, verapamil, amlodipine, large doses of progesterone, and, most classically, phenytoin (**Table 56-8**).[14,104-144]

Table 56-8 Agents Implicated in Drug-Induced Gingival Hyperplasia[14,104-144]

Drug	Incidence	Level of Evidence[a]
Amlodipine[14,121-125]	2–10%	B
Carbamazepine[126]	NK	C
Co-trimoxazole[14]	NK	C
Cyclosporine[14,104-109,127-131]	4–16%	A
Diltiazem[14,117-119,125]	21–76%	A
Diphenoxylate[14]	NK	C
Erythromycin[14,132]	NK	C
Ethosuximide[14,125]	NK	C
Felodipine[14,125]	<0.5%	C
Interferon α[14,133]	NK	C
Ketoconazole[14]	NK	C
Lamotrigine[14,134]	NK	C
Lithium[14,135-138]	NK	B
Mephenytoin[13,125]	NK	C
Methsuximide[125]	NK	C
Nicardipine[125]	NK	C
Nifedipine[14,111-117,121,122,125,129]	0.5–40%	A
Nimodipine[125]	NK	C
Nisoldipine[125]	<1%	C
Oral contraceptives[14]	NK	C
Phenobarbital[14,139]	NK	C
Phensuximide[125]	NK	C
Phenytoin[14,120,125,134]	10–80%	B
Primidone[14]	NK	C
Sertraline[14]	NK	C
Sodium valproate[14,110,125,140]	NK	B
Tacrolimus[127,141]	NK	C

Topiramate[14]	NK	C
Tranexamic acid[142]	NK	C
Verapamil[14,125,143]	19%	B
Vigabatrin[14,144]	<1%	C

NK - not known.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials;

Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

EPIDEMIOLOGY

The incidence of medication-induced gingival hyperplasia varies with medication class and specific agents within those classes. The incidence of gingival hyperplasia associated with calcium-channel blockers ranges from 3% to 6%, with some reports suggesting an incidence as high as 80%.[124,145] Up to 50% of patients treated with phenytoin will experience this gingival hyperplasia after the first 3 months of treatment.[146-148] Cyclosporine-induced gingival hyperplasia can affect 25–50% of adults and 70–97% of children.[149]

Table 56-9 Mechanisms of Drug-Induced Gingival Hyperplasia

Drug	Mechanism(s)[125]
Anticonvulsants	• Down regulation of epidermal growth factor receptor metabolism • Increased production and secretion of collagenase • Increased production of platelet-derived growth factor • Increased rate of cell growth • Interference of folic acid absorption and metabolism
Cyclosporine	• Altered gingival fibroblast metabolism • Immunogenetic predisposition (presence of HLA-DR2) • Increase in protein synthesis and cell proliferation • Increased activation of growth factors • Increased platelet-derived growth factor messenger RNA
Calcium-channel blockers	• Increased cell proliferation rate • Increased collagen synthesis • Interferences of calcium transport and calcium-dependent processes (i.e., collagenolytic effects of inflammatory cells, synthesis of collagenase)

RNA = ribonucleic acid.

MECHANISMS

The primary mechanism of drug-induced gingival hyperplasia is thought to relate to inflammation. (**Table 56-9**).[125] Inflammation may develop due to direct toxic effects of the drug in gingival fluid[150] or may be plaque-induced.[151,152] Decreased cellular folic acid uptake leads to decreased activity of collagenase and upregulation of keratinocyte growth factor, resulting in gingival overgrowth.[150,153] Once overgrown tissue develops, bacteria persist in pockets unable to be reached with a toothbrush or dental floss, which further perpetuates the cycle of inflammation.[154]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Gingival hyperplasia is characterized by increased gingival mass and volume that can be localized or generalized (Table 56-3).[125,154,155] Initial presentation may be a firm nodular enlargement which progresses to an enlarged, lobulated appearance. Gingival hyperplasia related to the use of calcium-channel blockers usually begins about 2–3 months after treatment initiation.[155] Cyclosporine-induced gingival hyperplasia is more likely to cause bleeding from the gums as compared to gingival hyperplasia caused by phenytoin.[149]

Differential diagnosis for drug-induced gingival hyperplasia includes systemic conditions such as certain types of leukemia, hereditary gingival fibromatosis, sarcoidosis, Crohn disease, Wegener granulomatosis, amyloidosis, pregnancy, hypothyroidism, or vitamin C deficiency (Table 56-4).[156] In patients with leukemia, other features of the gingival hyperplasia include oral ulcers, spontaneous bleeding, and candidiasis. When gingival hyperplasia is due to vitamin C deficiency, the gums often have a bluish-red color, with a smooth, shiny surface that bleeds easily.[157] In addition to decreased serum ascorbic acid levels (<2 mcg/mL), patients may have elevated levels of high-sensitivity C-reactive protein.[158] Additional conditions to rule out include gingival cysts and pregnancy-induced hyperplasia.[157] A biopsy with histologic exam may be necessary in some instances to establish the proper diagnoses.

RISK FACTORS

Underlying gingival inflammation due to poor oral hygiene and dental plaques may increase risk of drug-induced gingival hyperplasia (Table 56-5).[126,139,159] Men are more likely to develop gingival hyperplasia than women.[160] Exposure to a combination of medications such as cyclosporine and calcium-channel blockers may increase risk.[128,129] A prior history of developing gingival hyperplasia, weight gain, acne, hirsutism, or alopecia with the use of an anti-epileptic medication is associated with an increased risk of experiencing the same or additional side effects with repeat medication exposure or use of a different medication (37% chance with prior history versus 3% chance with no prior history).[134]

Genetic mutations are thought to play a role in the development of gingival hyperplasia. Mutations in the cytochrome P450 2C9 (CYP2C9), an enzyme encoded by the *CYP2C9* gene, have been associated with an increased risk of phenytoin-induced gingival hyperplasia (specifically, variant genotypes CYP2C9FNx012 and FNx013).[161] Polymorphisms of certain genes that modify the inflammatory response (e.g., MDR1 G2677T/A) have been associated with an increased likelihood of developing gingival hyperplasia due to calcium-channel blockers.[162]

MORBIDITY AND MORTALITY

The aesthetic effects of gingival hyperplasia are often all that are considered, but the presence of this drug-induced disease can lead to difficulty with speaking and chewing, worsened oral hygiene, and even malnutrition.[139,150,159] Although the medications do not typically affect the underlying bone, accumulation of bacteria within the pockets created by the gingival hyperplasia may lead to periodontitis and bone and tooth loss.[154] Children in particular may develop abnormal swallowing and have difficulty with speech and chewing.[163]

PREVENTION

Limiting the length and amount of drug exposure is the most effective method for prevention of all oral manifestations of systemically administered drugs (**Table 56-10**).[164,165]

Table 56-10 Approaches to Help Prevent Drug-Induced Gingival Hyperplasia

Drug	Approach
All	• Limit exposure (dose and duration) to drugs known to cause gingival hyperplasia • Prevent plaque-induced inflammation by good oral hygiene and preventative dental care
Phenytoin	• Folic acid supplementation[164,165]

Limited data suggest that the addition of folic acid to patients receiving phenytoin therapy may prevent the development of gingival hyperplasia.[164,165]

Because dental plaque plays such a large role in the development of gingival inflammation, patients receiving medications known to have a high incidence of gingival hyperplasia should be encouraged to follow a strict oral hygiene regimen, including plaque removal.[126]

MANAGEMENT

Primary treatment includes discontinuing the offending agent and performing good oral care. Surgery is usually unnecessary, but if required, gingivectomy or periodontal flap procedures would be the preferred options.[150,166] Nonsurgical dental procedures, such as scaling and root planing of dental plaques and calculi, may help reduce the inflammatory component of gingival hyperplasia.[154] For patients in whom discontinuing the offending agent is not a feasible option, there have been reports of improvement in gingival hyperplasia symptoms with the use of azithromycin 250 mg orally for 3–5 days.[167-171]

INFORMATION FOR PATIENTS

Healthcare providers should be knowledgeable about medications known to induce gingival hyperplasia. When patients are prescribed an agent with the potential to cause this drug-induced disease, they should be educated regarding the importance of good oral care to help minimize risk.

ORAL ERYTHEMA MULTIFORME

Drug-induced erythema multiforme (EM) is an adverse reaction to systemic drugs that manifests as skin lesions. Erythema multiforme can be categorized as minor, major, or oral based on the severity and number of sites involved. EM minor is typically a localized eruption of the skin with minimal or no mucosal involvement, while EM major is more severe, potentially life-threatening, and often includes extensive mucosal involvement. With oral EM, patients have typical oral and lip lesions without lesions elsewhere on the skin.

CAUSATIVE AGENTS

The most common triggers of EM include the sulfa drugs and anticonvulsants; however, multiple other medications such as allopurinol, carbamazepine, and clindamycin, have also been implicated.[14,172-175] **Table 56-11** lists drugs associated with oral EM.[14,22,172-185]

Table 56-11 Agents Implicated in Drug-Induced Oral Erythema Multiforme[14,22,172-185]

Drug	Incidence	Level of Evidence[a]
Abacavir[176]	NK	C

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials;

Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

EPIDEMIOLOGY

Although the prevalence of EM is estimated to be <1% (estimated incidence of 0.8–6 cases per million individuals per year), it is thought to account for about 6% of all autoimmune disease of the oral mucosa.[175,186] Approximately 90% of the cases of EM (all types) are triggered by an underlying herpes simplex virus (HSV) infection. Mucosal lesions may occur in 25–60% of patients with EM. Drug-induced EM accounts for <10% of all cases and usually presents as an isolated episode, rather than a recurrent or persistent condition.[187]

MECHANISMS

The exact mechanisms responsible for drug-induced oral EM are unknown (**Table 56-12**).[172,187] Erythema multiforme is a Type 4 hypersensitivity reaction that involves T-lymphocyte-induced apoptosis in epithelial keratinocytes, which leads to cell necrosis.[172] A component of the mechanism is a cell-mediated immune reaction against an antigen.[187] It has been found that the epidermal destruction with drug-induced EM is due to the cytokine tumor necrosis factor alpha, perforin, and granzyme B.[187,188]

Table 56-12 Mechanisms of Drug-Induced Oral Erythema Multiforme

- Cell-mediated immune reaction against an antigen[187]
- Epidermal destruction due to the action of tumor necrosis factor alpha, perforin, and granzyme B[187]
- Hypersensitivity reaction[172]
- T-lymphocyte induced apoptosis[172]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Clinical presentation can vary from patient to patient, with lesions changing and evolving throughout the course of an eruption (Table 56-3).[172,189,190] Fever may or may not be present prior to the onset of lesions, but oral EM often presents acutely, with no prodrome and no widespread cutaneous involvement.[180] The earliest lesions usually resemble insect bites or urticaria, which may then enlarge and transform into the characteristic targetoid lesion.[187,191] These lesions include a central area of necrosis surrounded by a red inflammatory area and a lighter erythematous periphery.[189,190] Oral lesions may also present as erythema with some edema and progress to superficial erosions.[189] The initial occurrence of oral EM is typically limited to oral mucosal ulcerations and lip lesions, without any skin lesions or systemic symptoms. Subsequent episodes may involve more extensive body areas.[174,180,192] In oral EM, the skin and mucosal surface of the lips are the most commonly affected areas of the oral cavity.[175] Lips may become swollen, cracked, bloody, and crusted.[172]

Conditions to consider in the differential diagnosis of oral EM include urticaria, Stevens–Johnson syndrome, fixed drug eruptions, Sweet syndrome, Rowell syndrome, herpes infection, and autoimmune lesions (i.e., pemphigus vulgaris, bullous pemphigoid) (Table 56-4).[187] The diagnosis of EM is generally made based on patients' clinical presentation. There is typically little need for culture or other laboratory testing.[193]

RISK FACTORS

HSV 1 and 2 are very common triggers of EM (reported in up to 90% of EM cases). Mycoplasma pneumonia infection may also trigger an EM eruption.[194] There is, however, no evidence to suggest infection with these agents increases the risk of drug-induced oral EM. Adults in their 20s are most at risk for EM, with a slightly higher risk in men than in women.[195] There appears to be a genetic component to erythema multiforme, with a link to specific human leukocyte antigen (HLA) types HLA-DQ3, HLA-B15 (B62), HLA-B35, HLA-A33, HLA-DR53, and HLA-DQB1*0301 (Table 56-5).[179,195]

MORBIDITY AND MORTALITY

Mortality from oral EM has not been reported. Although initial reactions may be limited to the oral cavity, repeat outbreaks may cause more widespread lesions. Systemic EM can progress to Stevens–Johnson syndrome, an extensive blistering disease of two or more mucous membranes that causes the top layer of affected skin to be shed. Stevens–Johnson syndrome can be life-threatening. Pain caused by mucosal erosions in patients with EM can lead to poor oral intake of food and fluids. Esophagitis with esophageal strictures and upper airway erosions that lead to pneumonia are rare complications.[187,190]

PREVENTION

Limiting the length and amount of drug exposure is the most effective method for prevention of all oral manifestations of systemically administered drugs. No other specific preventive measures for drug-induced oral EM have been identified.

MANAGEMENT

In general, no specific treatment is needed for drug-induced oral EM, as lesions typically resolve in 2–4 weeks following removal of the offending agent. Severe cases may be associated with poor oral intake, requiring hospital admission for pain management and fluid and electrolyte replacement. Erythrocyte sedimentation rate, white blood cell count, and liver enzymes may be elevated in severe cases.[189,190] Oral anesthetic solutions (e.g., viscous lidocaine) and antiseptic rinses (e.g., chlorhexidine) can be used for temporary relief of healing oral lesions. Severe mucosal EM may require an oral corticosteroid burst (e.g., prednisone 40–60 mg/day tapered over 2–4 weeks).[187] Occasionally, systemic and/or topical antibiotics may be required to prevent secondary infection.

INFORMATION FOR PATIENTS

Patients with underlying HSV infections are at an increased risk of developing drug-induced oral EM. Patients receiving drugs known to be associated with oral EM should be instructed to notify their healthcare provider immediately if and when oral lesions begin to develop.

ORAL LICHENOID DRUG REACTIONS

Lichen planus (LP) is a chronic mucocutaneous inflammatory disorder of unknown etiology for which there currently is no cure. Oral lichenoid reactions (OLRs) are a variant of LP that can be due to drug exposure, local contact hypersensitivity, altered self-antigens, or superantigens. Oral lichenoid lesions can present with a wide range of features.

CAUSATIVE AGENTS

Drugs that may be associated with OLRs include nonsteroidal anti-inflammatory drugs, angiotensin converting enzyme inhibitors, allopurinol, methyldopa, β-blockers, glipizide, ketoconazole, sulfasalazine, and lithium, among others (**Table 56-13**).[14,72,196-221]

Table 56-13 Agents Implicated in Drug-Induced Oral Lichenoid Reactions

Drug	Incidence	Level of Evidence[a]
Abatacept[202]	NK	C
Adalimumab[203,204]	NK	C
Allopurinol[14,72,198,200,205,206]	NK	B
Aminosalicylate sodium[201]	NK	C

[a]Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

EPIDEMIOLOGY

The incidence of OLRs is not clear. They may occur as a result of systemic drug exposure or local allergic contact.[201] OLRs may be clinically indistinguishable from oral LP, leading to difficulty with accurate diagnosis.

MECHANISMS

OLRs represent a hypersensitivity disorder to circulating antigens or local irritants.[225] There is a component of T-cell mediation via an autoimmune process in which $CD8^+$ T cells trigger apoptosis of oral epithelial basal cells. Medication-related OLRs are thought to be due, at least in part, to the active thiol group found in the chemical structure of certain medications.[208,228] Another potential factor for the development of OLRs is related to polymorphisms of cytochrome P450 enzymes (CYP), specifically involving CYP-2D6, which leads to decreased metabolism of some medications (**Table 56-14**).[224-227]

Table 56-14 Mechanisms of Drug-Induced Oral Lichenoid Reactions

- Cytochrome P450 (CYP)-2D6 polymorphisms leading to decreased metabolism of medications[226,227]
- Cytokine upregulation and lymphocyte recruitment[224]
- Hypersensitivity reaction to antigens or local irritants[223,225]
- Mast cell degranulation[224]
- T-cell mediated destruction of epithelial basal cells[224]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

OLRs are commonly associated with ulcerations along the buccal mucosa and lateral borders of the tongue that contain characteristic white striations known as Wickham striae (Table 56-3).[2,74,229,230] Pain usually accompanies the development of the ulcerations, although they may present as asymptomatic white reticular striae and plaques or painful swollen, red, eroded, or ulcerated lesions.[229] The onset may be slow and patients may initially report a roughness on the lining of the mouth and sensitivity to hot or spicy foods as their first symptoms.[230]

The principal condition to consider in the differential diagnosis of an OLR is oral LP (Table 56-4).[201,222,231] Other conditions to rule out would include malignancy, graft versus host disease, lupus erythematosus, and chronic ulcerative stomatitis.[222] It has been suggested that a diagnosis based on a history of recent exposure to an inducing medication combined with consistent physical findings is appropriate, although well-established ulcerations may persist long after the culprit medication is discontinued.[200,232] Biopsy of lesions caused by OLRs should contain immunoglobulin M and occasionally immunoglobulin A, immunoglobulin G, complement component 3, and colloid bodies containing fibrin.[206] Histopathological features of the biopsy specimen may include hyperkeratosis, basal cell degeneration, and band-like inflammatory cell infiltration.[229]

RISK FACTORS

Few known risk factors have been linked to the development of OLRs (Table 56-5).[208,228,233] OLRs are more common in women, with a highest risk between the ages of 30 and 70 years.[233] There may be a higher incidence of this reaction when medications contain a thiol group as part of their chemical structure.[208,228]

MORBIDITY AND MORTALITY

Mortality is unlikely with OLRs. The presence of OLRs have been associated with moderate-to-high levels of self-reported anxiety.[234]

PREVENTION

Limiting drug exposure (dose and duration) is the most effective method for prevention of all oral manifestations of systemically administered drugs, including OLRs.

MANAGEMENT

The most effective management strategy is removal of the causative agent. If this cannot be accomplished, the use of topical corticosteroids is recommended to help control symptoms. Corticosteroids are believed to act through their anti-inflammatory and immune-modulating properties. Beneficial results with medium- to super-potency topical agents such as clobetasol propionate 0.05% and betamethasone propionate 0.05% have been reported.[201] Topical aloe vera has also been studied and may provide some pain relief.[235,236] Mucosal protectants such as milk of magnesia may provide temporary relief. Immunosuppressive agents may be necessary in severe cases.[230] Topical tacrolimus has been studied and found to be an effective option for reducing signs and symptoms of OLRs as an alternative to topical steroids, particularly if patients are at risk for oral candidiasis.[237] Topical acitretin may be used as well.[237,238] Good oral hygiene should be encouraged to avoid infections.[239]

INFORMATION FOR PATIENTS

Reactions typically occur within the first 3 months of medication exposure but may be delayed up to a year.[201] Patients receiving drugs known to be associated with OLRs should be instructed to report any signs or symptoms of oral ulceration to their healthcare provider.

OSTEONECROSIS OF THE JAW

Cases of osteonecrosis of the jaw have become more common over the last decade due primarily to the widespread use of bisphosphonates.

CAUSATIVE AGENTS

Drug-induced osteonecrosis of the jaw has been commonly associated with the use of bisphosphonates, denosumab, bevacizumab, and sunitinib. These and other agents implicated in drug-induced osteonecrosis of the jaw are listed in **Table 56-15**.[240-254]

EPIDEMIOLOGY

The risk of osteonecrosis varies by causative agent. It has been reported in 5–12% of patients receiving bisphosphonates for treatment of metastatic malignancies.[255,256] The incidence in patients receiving zoledronic acid has been reported to be about 10%, with cumulative hazard ranging from 1% in the first year to 21% by 3 years. The overall risk with pamidronate appears to be lower, with a cumulative hazard ranging from 0% in the first year of treatment to 4% in the third year of treatment.[256,257] The reported incidence of bevacizumab- and sunitinib-induced osteonecrosis (<0.001%) is significantly less than that reported for bisphosphonates.[258]

Table 56-15 Agents Implicated in Drug-Induced Osteonecrosis of the Jaw

Drug	Incidence	Level of Evidence[a]
Alendronate[241,249]	0.017–0.03%	C
Bevacizumab[243-245,250,251]	NK	B
Denosumab[242,251]	1.8%	C
Etidronate[249]	NK	C
Ibandronate[249]	NK	C
Pamidronate[241,249,252,253]	Up to 18%	B
Risedronate[249]	NK	C
Sunitinib[243,246-251,254]	<1%	B
Tiludronate[249]	NK	C
Zoledronic acid[241,249,252]	1.6–2.8%	B

NK = not known.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

MECHANISMS

The mandible and maxilla have a greater blood supply (leading to relatively high concentrations of the drugs associated with osteonecrosis) and faster turnover than other bones. Multiple mechanisms are thought to possibly play a role in bisphosphonate-induced osteonecrosis of the jaw, including osteoclast inhibition leading to loss of maintenance of the capillary network within the bone and to insufficient bone deposition and remodeling, downregulation of matrix metalloproteinases, and increased osteoclast apoptosis and prevention of osteoclast development from bone marrow precursors and monocytes.[259-262] A spontaneous mucosal breakdown, injury, or invasive jaw surgery can cause bone exposure and failure of healing in necrotic bone.[241]

Osteonecrosis caused by denosumab, bevacizumab, and sunitinib is related to a drug-induced decrease in bone turnover and inhibition of host defense mechanisms. Denosumab is known to act on receptor activator of nuclear factor kappa-B ligand (RANKL) to inhibit the formation and activity of osteoclasts.[263-265] Bevacizumab targets vascular endothelial growth factor (VEGF) and prevents blood vessel growth, and sunitinib interferes with VEGF receptors leading to inhibition of neoangiogenesis.[250,254] Possible mechanisms for drug-induced osteonecrosis of the jaw are listed in **Table 56-16**.[259-265]

Table 56-16 Mechanisms of Drug-Induced Osteonecrosis of the Jaw

Drug	Mechanism(s)
Bisphosphonates	• Down-regulation of matrix metalloproteinases[260] • Increased osteoclastic apoptosis • Osteoclast inhibition leading to insufficient bone deposition and remodeling[259] • Prevention of osteoclast development[261,262]
Bevacizumab	• Prevention of blood vessel growth via VEGF[250]
Denosumab	• Inhibition of formation and activity of osteoclasts via RANKL[263-265]
Sunitinib	• Inhibition of neoangiogenesis via VEGF[254]

RANKL = receptor activator of nuclear factor kappa-B ligand, VEGF = vascular endothelial growth factor.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Clinical presentation of drug-induced osteonecrosis of the jaw may include asymptomatic exposed bone discovered on oral exam, exposed bone with associated pain, mobile teeth, cutaneous fistula, mucosal fistula, or bone exposed through the skin (Table 56-3).[241,266,267] Absent or delayed tissue healing after dental extractions may be one of the first signs.[266,267] Early stages of drug-induced osteonecrosis cannot be detected via x-ray.[266] Oral lesions may form with as little as 4 months of exposure to bisphosphonates, but the average time to onset is 9–14 months following medication initiation.[241,268,269] The time course for onset of osteonecrosis due to the nonbisphosphonates has not been fully elucidated. Osteonecrosis can affect both the maxilla and the mandible, with the mandible affected more often.[240] Once osteonecrosis has developed, colonization or infection with *Actinomyces* may occur. Actinomycosis is a chronic, polymicrobial infection that leads to frequent abscess formulation and multiple fistulae.[270,271]

Conditions to consider in the differential diagnoses of drug-induced osteonecrosis include fungal infection secondary to immunocompromised status in patients receiving chemotherapy and osteoradionecrosis (Table 56-4).[249]

RISK FACTORS

The greatest risk factors for the development of drug-induced osteonecrosis of the jaw include a duration of exposure to causative agents >6 months and the formulation of the bisphosphonate selected (Table 56-5).[240,249,251,257,266] Intravenous bisphosphonate administration has been associated with a greater risk than oral preparations.[249] One meta-analysis found that of 383 reports of bisphosphonate-associated osteonecrosis, 94% of the patients were receiving an intravenous bisphosphonate (primarily as treatment for various forms of cancer) while only 15 patients were receiving an oral bisphosphonate for the treatment of osteoporosis.[269] Combination treatment with a bisphosphonate and bevacizumab or sunitinib has been shown to increase the risk of osteonecrosis development while decreasing the latency period.[251] Additional risk factors include the presence of multiple myeloma, cancer that has metastasized to the bone, dental extractions, surgical bone manipulation, trauma from dentures, presence of oral infections, and overall poor oral health.[266]

MORBIDITY AND MORTALITY

Mortality attributed directly to drug-induced osteonecrosis has not been reported. However, drug-induced osteonecrosis often progresses despite treatment, leading to additional complications associated with cancer treatment and nutrition.[266]

Symptoms may range from nonexistent to severe, with severe cases causing pain, sequestration of bone, and sinus tracts that drain to the skin surface.[240,272] Necrotic exposed bone typically remains structurally strong enough to support normal daily jaw function, but may become secondarily infected, leading to pain, cellulitis, and fistula formation.[241] Paresthesia may develop if the area of osteonecrosis impacts the trigeminal nerve.[268]

Table 56-17 Approaches to Help Prevent Drug-Induced Osteonecrosis of the Jaw

Drug	Prevention

Bisphosphonates	• Avoid bisphosphonate initiation within 1 month of invasive dental procedures (i.e., tooth removal, periodontal surgery, root canal)[241] • Avoid tooth removal whenever possible[241] • Completion of dental care prior to treatment initiation[249] • Dental surveillance every 4 months while receiving bisphosphonate treatment[241]

PREVENTION

Limiting drug exposure (duration and dose) is the most effective method for prevention of all oral manifestations of systemically administered drugs. **Table 56-17** suggests additional steps that can be considered.[241,249] Whenever possible, dental work should be completed prior to initiating therapy with drugs known to cause osteonecrosis. The goal is to control existing oral disease (to help eliminate factors that could cause mucosal irritation) and to obviate the need for invasive dental procedures in the near future.[241,249] Bisphosphonate therapy should not be initiated within 1 month of invasive dental procedures (e.g., tooth removal, periodontal surgery, root canal therapy) to allow for bone recovery and healing. Dental surveillance every 4 months for patients receiving bisphosphonate therapy is recommended. In patients receiving bisphosphonate treatment, tooth removal should be avoided, and, if unavoidable, amputation of the crown and root canal treatment is a better option than full tooth extraction. If a tooth is demonstrating mild-to-moderate mobility, it should be splinted rather than removed. If the mobility is severe or an abscess is present, it is likely that osteonecrosis is already present and removal of the tooth and treatment with antibiotics is the best option.[241]

Screening to identify patients at risk for developing osteonecrosis is recommended. Assessment should include inquiries regarding current or past history of bisphosphonate use, changes in the mouth including odor, swelling, or discharge, and/or the presence of jaw pain or toothache.[268]

MANAGEMENT

Treatment of bisphosphonate-induced osteonecrosis of the jaw should be directed at eliminating or controlling pain and preventing progression of the exposed bone. Patients with exposed bone should be treated with long-term systemic antibiotics (e.g., penicillin, clindamycin) and an oral antimicrobial rinse (e.g., chlorhexidine gluconate) and should be closely followed. Antibiotics may need to be continued for more than a year and metronidazole may be necessary for patients who do not respond adequately to an initial course of antibiotics.[241,249] Extensive debridement may lead to larger areas of exposed, painful, and infected bone and should be avoided. Complete healing may not occur, but painful symptoms can be alleviated. If osteonecrosis of the jaw leads to the development of a cellulitis requiring intravenous antibiotics, treatment should include ampicillin–clavulanate, ciprofloxacin, or erythromycin, along with metronidazole.[241] There is no clear evidence demonstrating that discontinuation of bisphosphonate therapy leads to improved short-term healing because exposure persists due to the extended half-life of the medications. Bisphosphonate therapy should be discontinued in patients who develop osteonecrosis of the jaw except when a cancer-related indication for continued therapy exists.[241,266]

No specific treatment recommendations are available for osteonecrosis caused by nonbisphosphonate medications. Precautions should be taken when performing dental surgery or periodontal treatment in patients receiving bevacizumab, sunitinib, and denosumab.[251]

In contrast to radiation-induced osteoradionecrosis, hyperbaric oxygen therapy is not an effective treatment option for drug-induced osteonecrosis of the jaw.[268] Attempts to revascularize the bone may appear promising (with favorable initial response and healing), but long-term success is unlikely due to the extended period of time the drug remains concentrated within the bone.[273]

INFORMATION FOR PATIENTS

The risk of drug-induced osteonecrosis of the jaw is highest in patients receiving intravenous bisphosphonates for cancer treatment. The risk of developing this complication as a result of orally administered drugs used to treat osteoporosis is small. Patients receiving drugs known to be associated with osteonecrosis of the jaw should be encouraged to talk to their healthcare provider if they notice any changes such as ulceration, loose teeth, or exposed bone. Patients should be advised not to discontinue treatment with bisphosphonates without first talking to their healthcare provider.

CHAPTER 57

Neoplastic Diseases

Sandra Cuellar and Christina Mactal Haaf

Malignancy is an unfortunate known consequence of some medications. These malignancies can be aggressive and often lead to significant morbidity and mortality.[1,2] The agents most often implicated include those that alter the immune response (e.g., immunosuppressants), those that affect cellular proliferation (e.g., hormones, chemotherapeutic agents), and those that cause mutations (e.g., alkylating agents).

Drug-induced malignancies are difficult to study because they may not emerge until long after treatment with the culprit agent is completed. In addition, drug-induced malignancies may not occur frequently enough to permit definitive assignment of causality to particular agents. Many medications are given in combination, which can add to the difficulty in making a determination of causation, as can a number of patient-specific factors, including age and the presence of concomitant disease states.

Research in oncology has led to the unprecedented development of novel treatment and management strategies that incorporate tumor biology and cytogenetics. The field of oncology is dynamic and changes in management algorithms occur frequently. Therefore, referring to National Comprehensive

Cancer Network (NCCN) for current national treatment guidelines is recommended for healthcare providers who treat patients diagnosed with cancer.

LEUKEMIA

Therapy-related leukemia can arise from either lymphocytes or myeloid cells. The occurrence of acute lymphoblastic leukemia (ALL) after chemotherapy is rare; reports indicate these represent 1.2–2.5% of adult ALL cases.[3] The most common form of secondary leukemia is myeloid leukemia, which represents 8–10% of all acute myeloid leukemias (AML).[3] The World Health Organization updated the classification of myeloid neoplasms and acute leukemia in 2016.[4] In general, therapy-related myeloid neoplasms (t-MN) represent a heterogeneous and poorly defined group of patients with multiple and varied poor prognostic features. Patients with t-MN have poorer survival compared to those with de novo AML, myelodysplastic syndrome (MDS), or myelodysplastic syndrome/myeloproliferative neoplasm (MDS/MPN). MDS/MPN are forms of bone marrow failure that often evolve to AML.[5]

CAUSATIVE AGENTS

Table 57-1 lists the agents implicated in therapy-related leukemia; the most notorious include the alkylating agents and topoisomerase inhibitors. Several other culprits exist for t-MN. Those include azathioprine, lenalidomide (immunomodulatory agent), olaparib (poly ADP-ribose polymerase inhibitor), granulocyte colony-stimulating factor (G-CSF), and tumor necrosis factor (TNF) alpha inhibitors. TNF alpha inhibitors (infliximab, etanercept, adalimumab, certolizumab pegol, golimumab) have primarily been implicated in the development of lymphomas; however, case reports of AML have been observed in postmarketing settings.[6]

Table 57-1 Agents Implicated in Drug-Induced Neoplastic Diseases

Drug	Incidence	Level of Evidence[a]
LEUKEMIA[b]		
Azathioprine	NK	C
Cisplatin	NK	C
Cyclophosphamide/doxorubicin[147]	0.24–0.48%	B
Etoposide[12]	0.6%	B

Filgrastim (G-CSF)[25]	Up to 0.7%	B
Lenalidomide[30]	Up to 5.3%	B
MOPP[9]	2.9%	B
Olaparib[23]	1%	B
TNF alpha inhibitors	NK	C
LYMPHOMA[c]		
Antithymocyte globulin[148]	3%[d]	A
Azathioprine[148]	2.7%[e]	B
Cyclosporine[148]	2.4%[f]	B
Muromonab CD3 (OKT3)[149,150]	Up to 1.8%	B
Tacrolimus[148]	0.1%	B
TNF alpha inhibitors[151]	0.7%	A
SKIN CANCER[c]		
Antithymocyte globulin[149,150]	0.2%	B
Azathioprine[152]	11.2%[g]	B
BRAF inhibitors (dabrafenib, vemurafenib)[153]	15–30%	A
Cyclosporine[154]	1.2%[h]	B
Oral contraceptives[155,156]	6%	C
Muromonab CD3 (OKT3)[157]	1%	B
Selenium[68]	17%	A
Tacrolimus[158]	1.27%[i]	B
TNF alpha inhibitors[159]	Up to 30%	B
Voriconazole[160]	20%	B
BREAST CANCER		
Estrogen[88]	0.86%[j]	B
Estrogen + progestin[88,90]	0.41%[k] 1.53%[j]	A B
ENDOMETRIAL CANCER		
Estrogen[120]	Up to 40%[l]	B
Tamoxifen[161]	1.62%	A
BLADDER CANCER		
Cyclophosphamide[136]	Up to 10%[m]	B
Pioglitazone[133]	0.23%	B

BRAF = B-rapidly accelerated fibrosarcoma, G-CSF = granulocyte colony-stimulating factor, MOPP = mechlorethamine, vincristine, prednisone, and procarbazine, NK = not known, TNF = tumor necrosis factor.

[a] Definitions for Levels of Evidence: Level A—evidence from one or more randomized, controlled clinical trials; Level B—evidence from nonrandomized clinical trials, prospective observational studies, cohort studies, retrospective studies, case-control studies, meta-analyses and/or postmarketing surveillance studies; and Level C—evidence from one or more published case reports or case series.

[b] Incidence figures reported are often combined acute myelogenous leukemia/myelodysplastic syndrome.

[c] With the exception of BRAF inhibitors used for the treatment of skin cancer, the incidence figures for lymphoma and skin cancer are variable depending on organ transplanted, cumulative dose of immunosuppressants, concomitant immunosuppressants, and time since transplant. Intensity and duration of immunosuppression seem to be more closely correlated with risk than is use of any individual agent. Figures represented are for medication given in combination with other drugs on the list, as it is rare for these medications to be given alone. Refer to footnotes for details and text for further explanation.

[d] As induction prior to renal transplant, after 20 years of follow-up. Maintenance immunosuppressants included cyclosporine, prednisone, and azathioprine. Patients receiving same regimen without antithymocyte globulin induction had a 3% incidence after same duration of follow-up.

[e] Renal transplant recipients, at average follow-up of 86.5 months, combined with prednisolone.

[f] Renal transplant recipients, "normal dose" (trough concentrations 150–250 ng/mL) after mean follow-up of 5.5 yr of use alone (5%), with azathioprine (77%) or with prednisolone (18%). Lower incidence in comparator group (lymphoma, 0.86%; skin cancer, 14.7%) randomly assigned to "low-dose" cyclosporine (trough concentrations 75–125 ng/mL).

[g] Renal transplant recipients, at 2 yr, with mycophenolate mofetil and no induction.

[h] Renal transplant recipients, 17% also received azathioprine (follow-up variable; maximum, 10 yr).

[i] Renal transplant recipients, at 3 yr. Meta-analysis, all regimens included azathioprine or mycophenolate with or without steroids.

[j] After ≥10 yr of use.

[k] After average of 5.6 yr of use.

[l] Following only 1 year of unopposed estrogen use.

[m] Following median dose of 113 g, after 15 yr of follow-up.

The alkylating agents associated with t-MDS/t-AML include cyclophosphamide, ifosfamide, mechlorethamine, melphalan, busulfan, nitrosoureas, chlorambucil, dacarbazine, and platinum compounds such as cisplatin.[7,8] Mechlorethamine and melphalan are associated with a higher rate of t-AML than other alkylators. Previous Hodgkin lymphoma chemotherapy regimens that included mechlorethamine resulted in high rates of t-AML, whereas more modern doxorubicin-based regimens consisting of doxorubicin (Adriamycin), bleomycin, vinblastine, and dacarbazine (often referred to as ABVD) are not associated with increased risk.[7] Bhatia et al.[9] found the cumulative probability of leukemia 15 years after diagnosis of Hodgkin lymphoma to be 2.9% in patients who received mechlorethamine, vincristine, procarbazine, and prednisone (MOPP) as compared to 0.9% among patients who received ABVD for Hodgkin lymphoma. Therefore, the MOPP regimen is obsolete and ABVD is the standard of care for patients diagnosed with Hodgkin lymphoma. The topoisomerase inhibitors associated with t-AML include the epipodophyllotoxins (e.g., etoposide, teniposide) and the intercalating agents, mitoxantrone and doxorubicin. Mitoxantrone- and doxorubicin-associated t-AML have been reported in the literature; however, the incidence is not well defined.[10] The administration schedule of epipodophyllotoxins may be as important as, or even more important than, the cumulative dose. This theory of schedule-dependent elevated risk is plausible because epipodophyllotoxins are cell cycle-specific agents and differences in antitumor effect have been noted for different schedules. For example, administration of etoposide daily for 5 days is more active than 24-hour continuous infusion of the same total dose. Results from a study conducted by Pui et al.[11] suggested that patients who received weekly or twice weekly administration for prolonged periods were approximately 12 times more likely to develop AML versus other less frequent schedules. A Cancer Therapy Evaluation Program review also supported the theory that cumulative dose may not be as important as schedule. In their study, the likelihood of t-AML after treatment with epipodophyllotoxins was not dose-dependent. The 6-year cumulative incidence of t-AML in groups that received low (1.5 g/m^2), moderate (1.5–2.99 g/m^2), and higher (≥3 g/m^2) cumulative doses of etoposide was 3.3%, 0.7%, and 2.2%, respectively.[12] The risk of t-AML from regimens that include epipodophyllotoxins (such as etoposide) at doses of 5 g/m^2 or less administered daily for 2–5 days does not appear to increase. Therefore, most etoposide containing chemotherapy regimens include daily administration for 3–5 days.[10,12]

EPIDEMIOLOGY

According to the American Cancer Society, about 60,000 new cases of leukemia (all types) will be diagnosed in 2018. The exact incidence of therapy-related MDS/AML is unknown. Reports suggest that therapy-related MDS/AML account for 5–20% of all AML cases, which are the result of exposure to chemotherapy and/or radiation for treatment of a primary malignancy.[7,13,29] The incidence of MDS is not well defined in the literature. Therapy-induced ALL occurs less frequently than t-AML (incidence of approximately 1.2% versus 2.5%).[3]

t-AML is reported following the treatment of a variety of malignancies, including Hodgkin and non-Hodgkin lymphoma (NHL), ALL, breast cancer, ovarian cancer, and multiple myeloma. The incidence of t-AML after treatment of these diseases varies greatly, with the highest risk reported in patients who have been treated for Hodgkin lymphoma. In these patients, the incidence of AML may be 10- to 80-fold greater than that in the general population. The cumulative risk for MDS/AML in Hodgkin lymphoma is reported to be 0.3–10.2%, with a lower incidence associated with the doxorubicin-based regimen (ABVD) and a higher incidence related to use of a mechlorethamine-containing regimen such as MOPP. The cumulative incidence of MDS and/or AML among patients with breast cancer treated with the topoisomerase II-targeting drug, doxorubicin, and the deoxyribonucleic acid (DNA) alkylating agent, cyclophosphamide, has been reported to be 0.27%.[14] In a more recent study, the cumulative frequency was 0.24% at 5 years and 0.48% at 10 years. Patients included in the latter study were treated with four cycles of doxorubicin plus cyclophosphamide. Overall, the risk in breast cancer patients is small, and benefits outweigh risk. Testicular cancer represents another solid tumor in which there is an increased risk of t-AML after chemotherapy use at a cumulative dose of 650 mg of cisplatin (approximate relative risk of 3.2, 95% CI 1–8.4). The increased risk appears to be related to the cumulative dose of cisplatin rather than etoposide, with larger doses of cisplatin (≥1,000 mg) associated with approximately a sixfold increased risk. As with patients with other cancer types, patients with testicular cancer may receive therapies such as radiotherapy known to increase the risk of developing leukemia.[15]

Other chemotherapy agents such as azathioprine have also been linked to leukemogenesis. Azathioprine is classified as an antimetabolite. Unlike alkylating agents, antimetabolites do not damage DNA. Reports have largely involved patients with prolonged use of azathioprine to treat autoimmune conditions. The reported cumulative doses of azathioprine have varied from 19 to 400 g and the duration of use varied from 2 to 12 years. It is unclear whether the association between azathioprine and t-MN is dose/duration related. Published reports suggest that patients who develop t-MN may have other risk factors (e.g., use of other immunosuppressants and/or concomitant autoimmune diseases) that may contribute to the development of t-MN.[16]

The incidence of other therapy-related neoplasms such as AML and MDS has been reported with the use of lenalidomide in multiple myeloma patients.[17] Although other immunomodulatory agents, such as thalidomide and pomalidomide, are used to treat multiple myeloma, secondary neoplasms have been primarily reported with lenalidomide use in the maintenance treatment setting. In patients with multiple myeloma, maintenance therapy is proposed to control the proliferation of residual malignant cells after transplantation.[17-19] There are postmarketing case reports of t-MN with thalidomide and pomalidomide, and these agents are not used in the maintenance setting.[20,21] In clinical trials, patients treated with lenalidomide for multiple myeloma had increased risk of development of AML and MDS. One of the landmark trials that investigated lenalidomide maintenance therapy was among the first to report secondary malignancies. The pivotal phase III study was conducted in newly diagnosed multiple myeloma patients who received autologous stem cell transplants followed by consolidation treatment with lenalidomide (25 mg per day, on days 1–21 of each 28-day cycle for two cycles), followed by maintenance therapy with lenalidomide (10 mg per day for first 3 months, increased to 15 mg if tolerated). Treatment with lenalidomide continued until the patient progressed or unacceptable toxic effects occurred. The incidence of hematologic cancers (AML, MDS, Hodgkin lymphoma, and non-Hodgkin lymphoma) was 4% compared to 2% in the placebo arm. Of the patients who had secondary malignancies, several had received induction therapy with dexamethasone, cyclophosphamide, etoposide, and cisplatin or had undergone two transplantations and received lenalidomide maintenance therapy for at least 2 years.[17] The frequency of hematologic cancers was reported to be 5.3% in the newly diagnosed multiple myeloma patients who received lenalidomide in combination with oral melphalan. The frequency was approximately 5.2% following high-dose intravenous melphalan and autologous stem cell transplant. The reported frequency of AML/MDS was lowest (0.4%) when lenalidomide was combined with dexamethasone alone.[22] In the aforementioned studies, all patients had previous DNA damaging chemotherapy that might contribute to AML/MDS rates. This makes it difficult to ascertain which therapy is responsible for secondary malignancy.

Olaparib is a novel agent approved in the United States in 2014 for treatment of BRCA positive advanced ovarian cancer. MDS/AML was reported in 1% (22 of 2,618) of patients treated with olaparib across clinical trials. The duration of olaparib therapy varied from <6 months to >2 years.[23] All patients had previous DNA damaging chemotherapy, which may contribute to AML/MDS rates.

Knowledge of TNF alpha inhibitor–induced myeloid neoplasms, such as leukemia, is limited to information gleaned from case reports.[6]

MECHANISMS

In general, t-MN is thought to result from mutations induced by chemotherapy or by selection of a clone that has an increased risk of a mutation due to a certain phenotype (**Table 57-2**).[24] With respect to specific chromosome deletions, at least one and possibly two alleles of a tumor-suppressor gene may need to be deleted or inactivated. However, balanced translocations (e.g., involving the *MLL* gene at 11q23) can produce activation of fusion oncogenes that transform hematopoietic progenitor cells. The latter type of genetic transformation is thought to require a relatively smaller number of genetic events before becoming leukemogenic, perhaps explaining why t-AML associated with the use of topoisomerase inhibitors occurs earlier than with alkylating agents.[24]

Topoisomerase inhibitors block either the topoisomerase I or II enzyme, resulting in a permanent DNA strand break. Although the chromosomal breakage is important to the antineoplastic activity of these agents, it is also thought that these breakages result in chromosomal translocations that lead to secondary leukemia. In locations critical to transcription, such as the *MLL* gene, a change in the genomic function due to a translocation is likely important in the genesis of secondary AML. The rearrangements in the *MLL* gene occur within undifferentiated cells and can therefore result in lymphoid (e.g., in conjunction with chromosome 4) and myeloid (e.g., in conjunction with chromosome 9) leukemia.[7] The induction of t-AML with colony-stimulating factor use is thought to be related to the potential to promote proliferation of cells previously damaged by chemotherapy.[24] Patients diagnosed with congenital neutropenia experience lifelong low neutrophil counts and require long-term treatment with G-CSF. Long-term effects have been investigated in this population of patients. Although the data are unclear, a higher leukemic transformation rate (approximately 21%) has been reported in patients with severe congenital neutropenia. It is important to note that leukemic transformation has been reported in this patient population prior to G-CSF therapy. The precise role of G-CSF therapy in leukemic transformation remains unknown.[25]

Table 57-2 Selected Mechanisms of Drug-Induced Neoplastic Diseases

Drug	Mechanism
LEUKEMIA	
Carmustine	Cause DNA strand breaks resulting in chromosomal translocations/damage and alteration of key genes
Chlorambucil	
Cyclophosphamide	
Mechlorethamine	
Melphalan	
Doxorubicin	Induce translocations producing activation of oncogenes that transform hematopoietic cells
Epirubicin	
Etoposide	
Mitoxantrone	
Teniposide	
Filgrastim (G-CSF)	Induce proliferation of hematopoietic cells previously damaged by chemotherapy
Sargramostim (GM-CSF)	
LYMPHOMA	
Cyclosporine	Increases TGF-β and VEGF
Antithymocyte globulin	Suppression of immune surveillance, allowing proliferation of oncogenic viruses and inhibiting clearance of abnormal cells
Azathioprine	
Cyclosporine	
Muromonab CD3 (OKT3)	
Tacrolimus	
SKIN CANCER	
Cyclosporine	Increases TGF-β and VEGF

Antithymocyte globulin	Suppression of immunosurveillance, allowing proliferation of oncogenic viruses and inhibiting clearance of abnormal cells
Azathioprine	
Cyclosporine	
Muromonab CD3 (OKT3)	
Tacrolimus	
BREAST CANCER	
Estrogen	Covalent binding to DNA may cause mutations; metabolites act as tumor promoters; causes tumor cell proliferation via estrogen receptors
Progestin	Causes tumor cell proliferation via progesterone receptors
ENDOMETRIAL CANCER	
Estrogen	Induces proliferation of endometrium, which can transform to cancer
Tamoxifen	Induces proliferation of endometrium, which can transform to cancer; increases activation of pro-oncoenic genes; induces high mitotic rate in endometrial polyps
BLADDER CANCER	
Cyclophosphamide	Metabolites form DNA adducts, leading to mutation and carcinomatosis
Pioglitazone	Agonism of PPARs on urothelial cells in bladder

PPAR = peroxisome proliferator-activated receptor, TGF-β = transforming growth factor beta, VEGF = vascular endothelial growth factor.

The mechanism by which lenalidomide may increase risk of AML and MDS has not been fully elucidated. Unlike cytotoxic chemotherapy, lenalidomide shows no mutagenic potential in extensive genotoxicity studies performed during its development. Other complex issues in this patient population that may contribute to secondary neoplasms include treatment factors (previous alkylating agents, stem cell transplant, radiotherapy), myeloma-related factors, and host-related factors.[18,22,26]

Poly ADP ribose polymerase inhibitors are a relatively newer drug class in oncology. These agents have been investigated for use in several solid tumors, especially breast cancer and ovarian cancer. t-MN have been reported with olaparib use; however, the mechanism has not been fully elucidated. Previous therapy with alkylating agents may also contribute to secondary neoplasms in the ovarian cancer population.[23]

The mechanism by which G-CSF can cause leukemic transformation is not fully elucidated. The use of G-CSF is not limited to the oncology population, but also occurs with patients who have severe congenital neutropenia (SCN). These patients experience neutropenia for life and require long-term treatment with G-CSF. The SCN international registry reported a 10-year follow-up of SCN patients (n = 526) treated with G-CSF. They found that 21% of patients with SCN developed leukemia while being treated with G-CSF.[25]

Understanding the mechanism by which TNF-alpha inhibitors induce myeloid neoplasms is challenging for several reasons. Patients treated with TNF-alpha inhibitors likely have disease-related risk factors that predispose them for higher risk of cancer (such has previous therapies) as well as diseases that are associated with chronic inflammation that leads to chronic cellular proliferation. As a result, these patients are at higher risk for malignant processes. Diseases with chronic inflammation have been associated with a higher risk of development of both hematologic and solid tumor malignancies. Examples of diseases associated with chronic inflammation include rheumatoid arthritis, Crohn disease, and psoriasis.[6,27]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Signs and symptoms of t-MN are listed in **Table 57-3**. The diagnostic workup is identical for either de novo or t-AML and includes a complete blood cell count (CBC) with differential followed by a bone marrow biopsy or aspiration. t-AML typically occurs earlier than other types of secondary cancers, with time to presentation dependent on the causative agent used. There is usually a longer latency (3–8 years) between exposure to alkylating agents and the occurrence of t-AML compared to topoisomerase inhibitor-induced malignancy (typically presenting in 2–3 years). Patients who develop alkylator-related AML often present with MDS, although this rarely occurs in patients with AML-associated topoisomerase inhibitor use. Cytogenetic abnormalities are present in approximately 80% of patients with t-AML/t-MDS. The most commonly identified chromosomal abnormalities differ between drug classes. The most common abnormalities after treatment with alkylating agents are found in either chromosome 5, chromosome 7, or both, each of which undergoes complete or partial deletion. Balanced translocations involving the *MLL* gene on the 11q23 locus are the most common abnormalities with the use of topoisomerase inhibitors.[24]

Conditions that should be considered in the differential diagnosis of drug-induced myeloid neoplasms are listed in **Table 57-4**.

Table 57-3 Signs and Symptoms Associated with Drug-Induced Neoplastic Diseases

Leukemia

- Anemia
- Bone pain
- Bruising/bleeding
- Dyspnea on exertion
- Fatigue

- Fever/chills
- Leukopenia/leukocytosis
- Lymphadenopathy
- Thrombocytopenia
- Weight loss

Lymphoma

- Abdominal pain
- Anemia
- Chest pain
- Fatigue
- Fever
- Hepatosplenomegaly
- Lymphadenopathy
- Neutropenia
- Night sweats
- Thrombocytopenia

Skin cancer

- Abnormal sensation in skin
- Abnormal skin lesion (asymmetric, irregular border, abnormal color and/or texture, size >6 mm)
- Skin lesion that rapidly changes
- Skin ulceration, crusting

Breast cancer

- Abnormality in breast tissue (e.g., lump, erythema, induration)
- Breast pain/tenderness
- Nipple pain/tenderness
- Nipple retraction/discharge
- Upper extremity edema

Endometrial cancer

- Dysuria
- Pelvic pain
- Vaginal bleeding

Bladder cancer

- Dysuria
- Flank pain
- Hematuria
- Increased urinary frequency

Table 57-4 Conditions to Consider in the Differential Diagnosis of Drug-Induced Neoplastic Diseases

Leukemia

- Aplastic anemia
- Infection

Lymphoma

- Infection

Skin cancer

- Nonmalignant dermatologic disorder (e.g., psoriasis, eczema, actinic keratoses, seborrheic keratoses)

Breast cancer

- Nonmalignant breast cyst/calcification
- Nonmalignant dermatologic disorder
- Other malignancy (e.g., soft tissue tumors)

Endometrial cancer

- Endometriosis
- Pelvic inflammatory disease
- Uterine fibroids

Bladder cancer

- Hemorrhagic cystitis
- Urinary tract infection

RISK FACTORS

Risk factors for t-MN are listed in **Table 57-5**. Although the main risk factors for t-MN are exposure to certain types of anticancer drugs or radiation therapy, data also reveal a greater risk among patients with a prior cancer in general. This suggests an inherent increased susceptibility in this patient population, and several genetic factors thought possibly to confer increased risk are now being studied. Because t-AML develops in only a small proportion of patients exposed to alkylating agents or topoisomerase inhibitors, there are likely host factors that are critical to the development of this drug-induced disease. Polymorphisms in drug-metabolizing enzymes may be involved in susceptibility to t-AML. For example, the CYP3A4 wild-type genotype may result in increased production of reactive intermediate metabolites of epipodophyllotoxins that can damage DNA. Additionally, an increased rate of t-AML has been found among carriers of homozygous mutations in the *NQO1* gene.[7]

Table 57-5 Risk Factors for Drug-Induced Neoplastic Diseases

Leukemia

- History of malignancy
- Host factors resulting in individual susceptibility: polymorphisms in drug metabolizing enzymes

Lymphoma

- Advanced age
- Intense immunosuppression
- Long duration of immunosuppression
- Pretransplantation Epstein–Barr virus seronegativity
- Use of induction agents

Skin cancer

- Advanced age
- Exposure of skin to ultraviolet light
- Intense immunosuppression
- Light-colored skin
- Long duration of immunosuppression
- Prior skin cancer

Breast cancer

- Advanced age
- Body-mass index <25[a]
- Use of HRT, greater cumulative exposure to HRT, long duration of HRT

Endometrial cancer

- Conjugated estrogen use
- Greater cumulative exposure to estrogen and/or tamoxifen
- Long duration of estrogen use
- Obesity
- Pelvic radiation
- Pre-existing abnormal endometrial pathology

Bladder cancer

- Advanced age
- Extended duration of treatment with cyclophosphamide
- High cumulative doses of cyclophosphamide
- Smoking
- Extended duration of treatment with pioglitazone

HRT = hormone replacement therapy.

[a] Body-mass index is the weight in kilograms divided by the square of the height in meters.

MORBIDITY AND MORTALITY

The course of t-MN is progressive and the disease is typically resistant to the chemotherapeutic approaches used in the treatment of de novo leukemia. In general, t-MN is a fatal disease owing to marked and persistent cytopenias. Persistence of the underlying cancer can complicate treatment of the t-MN. Prior anticancer treatment can complicate the delivery of dose-intensive chemotherapy targeted at the t-MN by possibly causing significant organ and/or hematopoietic compromise. In addition, the high rate of cytogenetic abnormalities found in patients with t-MN often results in the abrupt development of drug resistance.[24]

PREVENTION

The primary preventive approach for t-MN involves avoiding the use of agents known to be linked to t-MN (Table 57-1) if possible. In the management of Hodgkin lymphoma, the preferred regimen, ABVD, contains agents with lower risks of t-MN development. This strategy has led to a much lower incidence of t-AML among patients treated for Hodgkin lymphoma. A similar approach has also been instituted in pediatric patients being treated for ALL, for whom epipodophyllotoxins have been removed from most first-line chemotherapy protocols. Sometimes drugs in the same class can deliver equivalent efficacy with lower leukemogenic risk. Examples include using cyclophosphamide (lower risk) instead of busulfan and substituting doxorubicin (lower risk) for mitoxantrone.

As previously noted, drug scheduling (e.g., with the epipodophyllotoxins) and cumulative dosing (e.g., with epirubicin and cisplatin) appear to be important factors to consider when designing chemotherapy regimens to mitigate the risk of drug-induced leukemia. Whether or not more judicious use of colony-stimulating factors (CSF) such as G-CSF should be considered is still debated. Although not negligible, the contribution of CSF to the absolute risk of drug-induced leukemia appears to be smaller than that of many chemotherapy agents.[24]

MANAGEMENT

There is little information available regarding optimal treatment of patients with t-MN. It is likely that a complete remission (CR) will be achieved in less than half of all cases, as compared with a CR rate of 65–80% in de novo AML patients 60 years of age or younger and 40–60% in patients older than 60 years of age. For patients who are candidates, the most likely curative approach is hematopoietic stem cell transplantation (HSCT). Small studies have reported 20–30% survival with HSCT. Patients over 40 years of age have a higher rate of transplant-related mortality.[28] Favorable, intermediate, and unfavorable karyotypes have been identified for cytogenetic abnormalities. Patients with secondary AML have a greater predominance of unfavorable types than patients with de novo AML (approximately 80% versus 20%). Mean survival among patients with secondary AML and the favorable type was approximately 27 months, but those with unfavorable features had a mean survival of only 6 months. With respect to specific cytogenetics, patients with secondary AML and abnormalities of chromosomes 5 and 7 appear to fare the worst.[24]

Treatment for patients with t-AML and a normal karyotype should follow standard AML management protocols with consideration of HSCT. Treatment consists of induction chemotherapy followed by consolidation therapy. For patients with unfavorable cytogenetics, either investigational chemotherapy approaches or

HSCT (or both) should be considered.[24,29] The NCCN provides the most up-to-date guidelines for health professionals on the management of myeloid leukemia cancers.

INFORMATION FOR PATIENTS

All patients receiving chemotherapy agents/regimens with a known potential for t-MN should be apprised of the risk and possible consequences at the outset. Patients diagnosed with t-MN should receive candid information regarding the likely outcome in relation to their risk group. Any treatment options should be carefully and thoroughly explained. Although it is important for patients to fully understand the seriousness of the disease so they can plan accordingly, it is also important for them to know that supportive measures are available and will be used to their fullest extent.

LYMPHOMA

There are two settings in which medication use has been associated with an increased risk of developing lymphomas: in transplant recipients and in patients treated for autoimmune disorders. The reported incidence of this drug-induced malignancy in immunosuppressed organ transplant recipients varies widely among the different registries and centers but may be as high as 50% after 6 years of follow-up. Lymphoproliferative disorders such as NHL and, less often, Hodgkin lymphoma occur in up to 20% of organ-transplant recipients.[2] Cases of these secondary malignancies have also been reported following lenalidomide maintenance use after stem cell transplantation in multiple myeloma patients.[30] The use of TNF-alpha blockers (adalimumab, certolizumab pegol, etanercept, golimumab, and infliximab) also poses an increased risk of lymphoma development, and this led to mandated boxed warnings in package inserts for these medications in 2009. Additionally, the U.S. Food and Drug Administration (FDA) released a safety announcement in 2011 describing cases of hepatosplenic T-cell lymphoma (HSTCL) occurring primarily in adolescents and young adults treated for Crohn disease and ulcerative colitis with tumor TNF-alpha blockers, azathioprine, or mercaptopurine.[31] This lethal T-cell lymphoproliferative disorder is rare and has been reported to have a clear association with immunosuppression with either an immunomodulator or combined immunosuppression with a TNF-alpha inhibitor and an immunomodulator.[32]

CAUSATIVE AGENTS

Immunosuppressive agents have been implicated in the development of lymphoma (Table 57-1).[22] Agents used in high doses for induction to facilitate transplant and as treatment for acute rejection are associated with a higher incidence of lymphoma in the first year after transplantation.[33,34] These agents include antithymocyte globulin and muromonab CD3 (OKT3), which was removed from the U.S. market in 2010. Maintenance immunosuppressants, including the calcineurin inhibitors, cyclosporine and tacrolimus, and the antimetabolite, azathioprine, are also associated with an increased risk of drug-induced malignancy. Although there are no reports of lymphoma with sirolimus or temsirolimus, a manufacturer of everolimus has a boxed warning alerting prescribers to the possible development of both skin cancer and lymphoma when the drug is used in the solid organ transplant setting.[35]

EPIDEMIOLOGY

In the first year after surgery, kidney transplant recipients have a 20 times increased risk of lymphoma and heart transplant recipients a 120 times increased risk, as compared with the general population.[34] The difference between the two groups is thought to be related to the more aggressive immunosuppression used in heart transplantation. Risk persists over time, with lymphoma developing in 1.6% of kidney transplant recipients over 10 years and 5.6% of heart–lung recipients over 5 years.[33] OKT3 or antithymocyte globulin induction increases the risk of lymphoma primarily during the first year after transplantation.[33,34] The majority of immunosuppressant-induced lymphomas are of B-cell origin, and 28% of patients have central nervous system involvement.[36] Patients <10 or >60 years of age have the highest risk for lymphoma.[33]

Post-transplant lymphoproliferative disorders (PTLD) are potentially fatal lymphoid and/or plasmacytic proliferations that develop in solid organ or allogeneic hematopoietic cell transplant patients due to immunosuppression. B cells that multiply in the absence of normal T-cell immune function in the stem cell transplant population are thought to be infected with the Epstein–Barr virus (EBV). Thus, PTLD generally refers to an EBV-induced B-cell proliferation that develops after a solid organ transplant or allogeneic HSCT. The incidence of EBV-PTLD after allogeneic HSCT ranges between 0.5% and 17%.[37]

Of the cancer cases related to the use of TNF-alpha inhibitors that were reported to the FDA from 1998 to 2008, half were Hodgkin and non-Hodgkin lymphomas, with 10 cases of HSTCL.[38] A meta-analysis in rheumatoid arthritis patients treated with TNF-alpha inhibitors found no increased risk of lymphoma when compared to nonexposed patients.[39]

MECHANISMS

There are multiple mechanisms by which immunosuppressants are thought to cause malignancy (Table 57-2). Calcineurin inhibitors such as cyclosporine can promote malignant growth by increasing the amount of tumor growth factor (TGF) and vascular endothelial growth factor (VEGF).[40] Immunosurveillance is suppressed in patients receiving immunosuppressants. Oncogenic viruses are not as readily cleared as in nonimmunosuppressed individuals. These factors together provide an optimal environment for malignant transformation of cells by viruses and subsequent proliferation of those cells. Specifically, cases of lymphoma in the post-solid organ and allogeneic stem cell transplantation settings have been associated with proliferation of the EBV within B lymphocytes.[2,37]

T lymphocytes and natural killer cells endogenously produce the cytokine TNF-alpha as part of a cell-mediated immune response during infections and cause tumor cell lysis. TNF-alpha was recognized in 1975 for its ability to lyse tumors in laboratory models, raising the concern that inhibition of this cytokine may lead to cancer development.[41] Conflicting clinical data exist regarding the role of TNF-alpha inhibition in the development of malignancy.[42]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Symptoms of lymphoma can include fatigue, weight loss, lymphadenopathy, and night sweats (Table 57-3). Diagnosis is made by node, tissue, or bone marrow biopsy; CBC with differential; and imaging studies (Table 57-4). NHL after immunosuppressive therapy is associated with increased extranodal involvement as compared to lymphomas in the general population.[36] In some patient subsets, extranodal disease occurs within or near the transplanted organ. Examples include disease of the liver in liver transplant recipients and disease of the lungs in heart, lung, or heart–lung transplant recipients.[34,35]

RISK FACTORS

Risk factors for drug-induced lymphoma are described in Table 57-5. The incidence of lymphoproliferative disorders increases proportionately with increasing dose and duration of immunosuppressant medications. Therefore, transplant procedures in which patients require the highest doses of immunosuppressants and the most aggressive antirejection strategies, such as heart and lung, are associated with the highest incidence of lymphoma.[34] This intensity–risk relationship was demonstrated by a prospective randomized trial of low-dose versus standard-dose cyclosporine therapy in kidney transplant recipients. A higher frequency of malignancy was found in the higher-dose group.[43] A study of heart transplant recipients revealed that cumulative doses of OKT3 (a medication no longer available in the United States) >75 mg imparted a 35.7% risk of lymphoma as compared with 6.2% in patients who received ≤75 mg.[44]

Advancing age and pretransplantation EBV seronegativity are additional risk factors.[45] Young children are more likely than adults to be EBV-seronegative prior to transplantation and are at risk for initial EBV exposure during or after transplantation. This puts them at high risk for post-transplantation lymphoma.[46]

MORBIDITY AND MORTALITY

Malignancy-related mortality after organ transplantation ranges from 10% to 47%. NHL after organ transplantation is more aggressive than in the general population, most likely because of the necessity to maintain immunosuppression and an advanced stage at presentation. First-year lymphoma-related mortality in kidney and heart transplant recipients was reported at 40% and 50%, respectively.[33]

Table 57-6 Approaches to Help Prevent Drug-Induced Neoplastic Diseases

Leukemia

- Avoid use of mechlorethamine in the treatment of Hodgkin lymphoma
- Avoid weekly scheduling of etoposide/teniposide and avoid use when other agents are equally effective
- Consider using cyclophosphamide instead of busulfan in chemotherapeutic regimens
- Consider using doxorubicin instead of mitoxantrone in chemotherapeutic regimens
- Limit cumulative dose of cisplatin in the treatment of testicular cancer
- Limit cumulative dose of epirubicin in the treatment of breast cancer

Lymphoma

- Consider using basiliximab for induction instead of antithymocyte globulin
- Consider using everolimus or sirolimus instead of cyclosporine or tacrolimus for maintenance immunosuppression
- Limit cumulative dose of cyclosporine or tacrolimus
- Monitor EBV levels for possible reactivation
- Use antiviral prophylaxis for 3 months after organ transplantation

Skin cancer

- Avoid ultraviolet light
- Consider using everolimus or sirolimus instead of cyclosporine or tacrolimus for maintenance immunosuppression
- Consider using mycophenolate mofetil instead of azathioprine for maintenance immunosuppression

Breast cancer

- Avoid use of HRT

Endometrial cancer

- Avoid use of tamoxifen
- Consider use of aromatase inhibitors instead of tamoxifen for the treatment of breast cancer
- Do not use tamoxifen for longer than 5 yr
- Use progestin concomitantly for at least 10 days /month with estrogen when used for HRT

Bladder cancer

- Limit cumulative dose cyclophosphamide to <20 g
- Use mesna as uroprotectant with cyclophosphamide[a]
- Avoid pioglitazone use for ≥24 months

HRT = hormone replacement therapy.

[a] Unproven in humans.

PREVENTION

Approaches to preventing drug-induced lymphoma are described in **Table 57-6**. Because drug-induced lymphoma is associated with the use of intense immunosuppression, transplant recipients should be maintained on the lowest possible doses of immunosuppressant drugs for the shortest possible time to reduce overall risk. There is some evidence that sirolimus, a mammalian target-of-rapamycin (mTOR) inhibitor, has antiangiogenic effects and is associated with fewer post-transplantation malignancies than cyclosporine or tacrolimus (0.6% versus 1.81% at a mean follow-up of 2.3 years). Induction with an interleukin-2 antibody such as basiliximab has not been definitively associated with an increased risk of lymphoma and may be an option to improve outcomes.[47] Antiviral prophylaxis with acyclovir for 3 months after transplantation has been shown in one study to be associated with a reduced incidence of post-transplantation lymphoma in heart transplant recipients, suggesting the potential utility of antiviral agents as a preventive strategy.[48] Acyclovir use in this setting is questionable due to the absence of activity against EBV associated with PTLD.[49]

MANAGEMENT

Dose reduction or discontinuation of immunosuppression is the primary method used to manage post-transplantation lymphoma; however, the risk of organ rejection must be carefully considered.[46] Surgical excision of localized lesions has been used with favorable results.[50] The anti-CD20 monoclonal antibody rituximab is an option for the treatment of B-cell lymphomas. Two studies in which patients with drug-induced lymphoma received rituximab 375 mg/m^2 once weekly for 4 weeks reported CR rates of 53–88%.[51,52]

Chemotherapy may be an option for patients who do not respond to reduction of immunosuppression. A primary treatment regimen for lymphoma consisting of cyclophosphamide, doxorubicin, vincristine (Oncovin), and prednisone (often referred to as CHOP) has been successfully used in the post-transplantation lymphoma population.[53] Many centers use anthracycline-based regimens, adjusting chemotherapy doses as necessary to address patient comorbidities.[54,55]

INFORMATION FOR PATIENTS

Patients should be educated regarding the possible adverse effects associated with drugs that will be used after transplantation, including the risk of lymphoma with immunosuppressants. Patients in whom post-transplantation lymphoma develops should receive candid counseling regarding the prognosis, available treatments, and the risks and benefits associated with each of the treatment options.

SKIN CANCER

Basal cell carcinoma (BCC) is the most commonly diagnosed skin cancer (approximately 80% of new cases), while 16% are squamous cell carcinoma (SCC), 2% melanoma, and <1% are Merkel cell carcinoma, Kaposi sarcoma, cutaneous lymphoma, skin adnexal tumors, or various sarcomas. Basal cell carcinoma and SCC are not reported to cancer registries because these cancers rarely metastasize and almost all cases can be cured, making incidence estimates more difficult.[13] Skin cancer is the most common malignancy in patients receiving immunosuppressive medications to prevent rejection of transplanted organs, with SCC the most common cutaneous malignancy in this population.[56]

CAUSATIVE AGENTS

Several medications are associated with the development of skin cancer, including TNF-alpha blockers, B-rapidly accelerated fibrosarcoma (BRAF) inhibitors, mitogen-activated protein kinases (MEKs), and extracellular signal–regulated kinases. (Table 57-1). Additionally, recent reviews found that the short-term use of several commonly prescribed medications that cause photosensitivity may enhance the risk of skin cancers such as BCC, SCC, and cutaneous lymphoma.[57,58]

It is thought that the level of immunosuppression itself, and not any one particular drug, is responsible for the increased risk of skin cancer in the transplant setting.[2,59,60] Patients who are recipients of transplanted organs or allogeneic stem cells receive the highest doses of immunosuppressant medications and are at the highest risk for drug-induced skin cancer.[61,62] It appears that it is the concomitant use of multiple therapies including immunosuppressants, myeloablative chemotherapy, and radiation that is responsible for SCC and BCC in allogeneic HSCT recipients.[62]

Currently available BRAF inhibitors, dabrafenib and vemurafenib, as well as MEK inhibitors, cobimetinib and trametinib, have revolutionized treatment and survival of metastatic melanoma in patients with the BRAF mutation but are associated with up to a 33% incidence of SCC, 6% incidence of BCC, and 2.4% incidence of new primary melanoma.[63-67]

Selenium supplementation among patients with a prior history of nonmelanoma skin cancer (NMSC) has been implicated as a potential cause of SCC in a double-blind trial. SCC has also been reported in case reports of oral contraceptives users.[68]

EPIDEMIOLOGY

Skin cancer occurs in organ transplant recipients at a rate of 12–90 times the frequency observed in the general population.[2] Patients with nonrenal transplants are 3 times more likely to develop skin cancer than those with renal transplants.[59] This is likely due to a strong relationship between skin cancer risk and intensity of immunosuppression, because kidney transplant recipients typically require less immunosuppression. In addition, transplant recipients are more likely than patients in the general population to present with multiple lesions. Older patients tend to present with skin cancer sooner after transplantation than younger patients. However, the incidence of skin cancer in all transplant patients increases linearly with time after transplantation.[59]

MECHANISMS

As with immunosuppression-induced lymphomas, reduced immunosurveillance plays a role in post-transplantation skin cancers (Table 57-2). Apoptosis of cells damaged by ultraviolet light may not occur as efficiently in immunosuppressed individuals as in the general population. The damaged cells remain and proliferate as skin cancer. Unchecked proliferation of human papillomavirus (HPV) has also been implicated, and studies have reported that skin lesions in organ transplant recipients are positive for HPV DNA in up to 100% of cases.[2,69,70] Although HPV vaccination has been recommended for solid organ transplant recipients who meet the FDA indication, poor immunogenicity has been reported in the post-transplant patient setting.[71,72] HPV has not been detected in skin lesions of patients treated with BRAF inhibitors. It is not known whether patients receiving anti-TNF-alpha therapy have an altered response to HPV vaccination.[73]

Although TNF-alpha may be a part of cell-mediated immune response, ultimately causing tumor cell lysis, clinical data regarding the role of TNF-alpha inhibition in the development of malignancy are conflicting. Meta-analyses support an increased risk of NMSC with the use of these medications although two large cohort studies revealed no statistical difference in the development of overall increased risk of NMSC between TNF-alpha inhibitor users and nonusers.[39,42,74]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Multiple other skin disorders can resemble drug-induced skin cancer (Table 57-4). Patients can present with multiple lesions that can be rapidly recurring (Table 57-3). Although lesions can occur anywhere on the body, they most frequently are found in areas exposed to sunlight.[63] Approximately 70% of skin cancers in both men and women occur on the head, neck, and upper extremities.[61,62]

Although in the general population BCC is more common than SCC, the opposite is true in immunosuppressed patients. In 1,293 kidney transplant recipients in whom skin cancer developed, 71% had SCC, 52% had BCC, and 3% had melanoma (some patients had more than one type of skin cancer).[39] An SCC:BCC ratio of 2.2:1 was found in a group of 48 heart transplant patients in whom skin cancer developed.[60] The reported median time to first appearance of cutaneous squamous cell carcinomas and keratoacanthomas in melanoma patients treated with BRAF inhibitors was approximately 8 weeks.[66,67]

The incidence of skin cancer increases linearly with time, with an incidence of 2.2%, 7.2%, and 8.9% at 5, 10, and 14 years, respectively, reported in kidney transplant recipients.[61] As noted previously, the incidence of skin cancer is higher in heart transplant recipients, with reported rates of 12%, 27%, and 44% at 5, 10, and 14 years, respectively.[60]

RISK FACTORS

As in the general population, persons with lighter skin are at a greater risk for drug-induced skin malignancies than those with darker skin. Exposure to ultraviolet light and advanced age are additional risks (Table 57-5).[41,60,61] As with post-transplantation lymphomas, there is a correlation between intensity and duration of immunosuppression and the development of skin cancer.[34,41,59] In a retrospective study of 262 patients, those who received cyclosporine in addition to azathioprine and prednisolone had NMSC at a rate of 48 cases per 1,000 patient-years, as compared with 27 cases per 1,000 patient-years in the azathioprine-plus-prednisolone-only group.[75] Patients who have had a prior skin cancer are at greater risk than those who have not.[41,76]

Ras protein mutation is a possible risk factor for developing SCC in patients treated with BRAF inhibitors, as this mutation was present in approximately 60% of cases in patients treated with vemurafenib.[46] Other possible risk factors associated with cutaneous SCC observed in vemurafenib clinical studies are age ≥65 years, history of prior malignancy, and chronic sun exposure.

Establishing the risk of the development of skin malignancies in patients receiving TNF-alpha inhibitors is challenging because most of these medications have been studied in patients with rheumatoid arthritis or ulcerative colitis, populations that are at increased risk for developing site-specific cancers. In addition, TNF-alpha inhibitor studies in these groups often allowed concomitant medications (e.g., cyclophosphamide or methotrexate), which augment malignancy risk.[1,43,74] There are fewer studies with certolizumab pegol and golimumab. Therefore, it is unknown if these newer TNF-alpha inhibitors pose the same risks of cancer development as adalimumab, etanercept, and infliximab.[77]

MORBIDITY AND MORTALITY

Mortality due to post-transplantation skin cancer has been reported to be 5%, which is higher than the 1–2% reported for the general population. Although the majority of lethal skin cancers in the general population are melanomas, SCC is the primary skin cancer responsible for death in the transplant population.[59] Skin cancers in transplant recipients are also typically more aggressive than those found in the general population: 6% of patients in the Cincinnati Transplant Tumor Registry had metastases, nearly three-fourths of which were from SCC.[59] A multicenter study of 68 patients with metastatic skin cancer (primarily SCC) reported a relapse rate of 29% after treatment and a 3-year survival rate of 54%.[78]

Patients' risk of mortality does not appear to be affected by treatment with BRAF inhibitors or TNF-alpha inhibitors. Progression-free survival among 134 patients with metastatic melanoma was not statistically different among patients who had developed a SCC and those who had not after 4 months of BRAF inhibitor therapy.[70] The overall survival in a study of rheumatoid arthritis patients treated with either adalimumab, etanercept, or infliximab (with or without concomitant disease-modifying antirheumatic drugs) and subsequently diagnosed with a solid tumor was not statistically different than survival in TNF-alpha treatment-naïve patients.[79]

PREVENTION

Methods to help prevent drug-induced skin cancer are presented in Table 57-6. Although there are no chemoprevention studies in subjects who have received TNF-alpha inhibitors or BRAF inhibitors, it would be prudent to suggest the same recommendation for skin cancer prevention that apply to the general population (i.e., sun avoidance and routine monitoring for unusual or new skin lesions).

Because of the strong relationship between intensity of immunosuppression and risk of skin cancer, maintaining patients on the lowest possible doses of immunosuppressants or using alternative agents may decrease the incidence in recipients of solid organ transplants. Azathioprine, when used as part of the immunosuppressive regimen in renal transplant patients, was linked to an increased risk of developing aggressive SCC.[80] Mycophenolate mofetil rather than azathioprine use in the immunosuppressive regimen may reduce the risk of skin cancer in some solid organ transplant recipients.[48,81] Additionally, the development of NMSC in the transplanted population has been associated with azathioprine use compared to those who did not receive this medication.[82] There has been some evidence that the mTOR inhibitors, sirolimus and everolimus, are associated with fewer cases of NMSC than cyclosporine or tacrolimus; however, long-term data are lacking.[76,83] Further studies are required to assess the impact of immunosuppressive therapy modifications on malignancies of the skin in solid organ transplant recipients.

MANAGEMENT

General treatment options for skin cancer include surgical excision of the lesion, immunotherapy, targeted therapy, chemotherapy, or radiation.[84] Surgery or radiation may not be plausible, however, in patients with multiple lesions or metastases. In these cases of transplanted patients, reduction of immunosuppression is an option, although the benefits of this approach are not as clear as they are in patients with drug-induced lymphoma. The risks of organ rejection must be carefully considered.[85] In 2006, guidelines for immunosuppressant dose reduction were released by a task force of the International Transplant Skin Cancer Collaborative and Skin Care for Organ Transplant Patients Europe.[86] The degree of dose reduction of immunosuppressants recommended for multiple clinical scenarios is outlined in these guidelines.

New primary SCC in melanoma patients treated with BRAF inhibitors can be treated with standard ablative or excisional surgical methods without interruption of the BRAF dosing regimen; for patients with multiple lesions, curettage, electrodesiccation, or cryosurgery has been suggested.[85]

Systemic therapy is typically reserved for cases in which surgical excision with or without radiation is either unsuccessful or deemed not beneficial.

INFORMATION FOR PATIENTS

Patients receiving immunosuppressive therapy for prevention of transplant rejection should be warned of the increased risk of skin cancer. They should be instructed to protect their skin from sun damage by use of sunscreen year-round and should also use protective clothing such as long-sleeved garments and hats. It is important to note that use of sunscreen does not negate the risk of skin cancer, so even with its use patients should still make every attempt to minimize their exposure to sunlight. Patients should never use tanning beds. Patients should inspect their own skin regularly for changes and also should be checked regularly by a dermatologist.[84]

Patients who are to receive BRAF inhibitors should be screened for skin cancer prior to initiation of therapy, every 2 months during treatment, and again following completion of therapy.[66,67]

BREAST CANCER

The American Cancer Society estimates that breast cancer kills nearly 41,000 women in the United States annually with nearly 253,000 new cases of this malignancy diagnosed.[13] This makes breast cancer the most common malignancy among women. Breast cancer can be drug-induced.[13]

CAUSATIVE AGENTS

Agents implicated in the development of breast cancer are listed in Table 57-1. The association between drug use and breast cancer development has been reported in patients receiving combination estrogen and progestin hormone-replacement therapy (HRT), estrogen-only HRT (ET), or oral contraceptives (OC). Menopausal state and exogenous hormone use may influence the risk of breast cancer development depending on the type of product used.

EPIDEMIOLOGY

Numerous studies have shown an association between a longer duration of HRT use and breast cancer development.[87] The Million Women Study, an observational study of 1,084,110 women, revealed a 43% increased risk of breast cancer among the 550,172 who received HRT versus those who did not.[88] The Women’s Health Initiative (WHI), a randomized, controlled trial involving 16,608 women, found those receiving combination HRT had a 26% higher risk of invasive breast cancer than patients in the control group.[89] Further analysis of these cases revealed a higher rate of invasive tubular (8%) and lobular (22%) breast cancers found in women using HRT compared with nonusers. The rate of breast cancer development in women receiving HRT exceeded that of control patients after approximately 3–4 years of use.[90] Other studies have demonstrated similar patterns.[91,92] Breast cancer risk declines after HRT use is discontinued.

The association between OC use and breast cancer is less clear. A large meta-analysis of mostly case-control studies that included 53,297 women with breast cancer and 100,239 women without breast cancer demonstrated a relative risk for breast cancer of 1.24 in current users of OC.[93] The risk did not approach that of women who had never used OC until 10 or more years after use was discontinued. The median year of first use in these pooled studies was 1968, with the majority of breast cancers subsequently diagnosed in the 1980s. The majority of women included in these studies used OC when estrogen doses were much higher than in those currently marketed, making extrapolation of these results to modern OC difficult. In 1996, the reported increase in relative risk accounted for few additional cancer diagnoses as compared with women who had never used OC: 0.5, 1.5, and 4.7 additional cases per 10,000 women who used OC between the ages of 16–19, 20–24, and 25–29 years, respectively.[94] A 2002 case-control study that included 4,575 women with breast cancer and 4,682 without showed no increased risk with current or former OC use.[93] A more recent meta-analysis of over 850,000 women demonstrated an insignificant association between OC use and breast cancer among women who are BRCA1 or BRCA2 mutation carriers compared to the general population.[95]

There are multiple theories as to how hormones can cause breast cancer (Table 57-2). Estrogen metabolites may covalently bind to DNA and cause mutations.[96] In vitro, quinone metabolites of equine estrogens (present in the most common oral formulations of HRT) act as carcinogens and tumor promoters.[97] Estrogens, progestins, and their metabolites can act on estrogen and progesterone receptors (ER/PR) on breast cancer cells, stimulating proliferation.[98,99] This mechanism is supported by the observation that hormone use has been significantly associated with the development of ER/PR positive breast cancers in multiple studies.[90,100]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Breast cancer most often presents as a painless lump within the breast tissue (Table 57-3). Any suspicious lump, whether painful or not, should be assessed by physical examination and imaged using mammography or other techniques, such as ultrasound. Breast cancer is confirmed by biopsy of affected tissue and nodes. Other conditions to consider in the differential diagnosis include benign breast disease or calcification and other malignancies. Although statistically significant increases in the risk of breast cancer are not typically found during the first 3–4 years of combination HRT, women have been diagnosed as early as during the first year.[90,94,100]

RISK FACTORS

Multiple risk factors associated with this hormone-induced malignancy are listed in Table 57-5. Although it appears that use of any HRT can lead to breast cancer, multiple studies have demonstrated an increased risk of all types of breast cancer in women receiving combination HRT as compared with estrogen-only HRT.[88,101-103]

A shorter time (<5 years) between menopause and HRT initiation is associated with a significant increase in the rate of breast cancer.[13] Incidence also increases linearly with greater cumulative exposure to HRT and with age.[91,103]

Although increased breast cancer risk ratios have been associated with obese, postmenopausal women who never took estrogen–progestin therapy, some studies have shown an inverse correlation between body-mass index (BMI; calculated as the weight in kilograms divided by the square of the height in meters) and risk, such that women taking HRT with a BMI <25 have a higher relative risk than those with BMI >25.[104,105]

Studies of risk in women with a family history of breast cancer or carriers of the BRCA1 mutation and the use of OC report conflicting results.[95]

MORBIDITY AND MORTALITY

The 5-year survival rate of American women with breast cancer ranges from close to 100% for those with stages 0 and I disease to 22% for those with metastatic disease.[106] Women receiving HRT in the WHI study were found to have tumors that were larger, more likely to be node-positive, and diagnosed at a more advanced stage than controls.[90] Data from a large prospective cohort of 374,465 women found that those who used combination HRT for at least 5 years had a relative risk of invasive tumor of 1.51 as compared with women who had never used HRT.[103] Consistent with these findings, a 2013 overview of the results from the two Women’s Health Initiative hormone therapy trials with extended postintervention follow-up revealed not only an increased breast cancer incidence in women using HRT but also diagnoses at higher cancer stages.[107] Despite this reported increased risk of occurrence, other studies have shown a better prognosis for patients who have a history of HRT use, with higher overall and disease-free survival rates.[108,109] Schuetz et al.[110] reported 5-year survival rates of 92.8% and 82.2% in HRT users and nonusers, respectively;in addition, metastases were more likely to occur in non-HRT patients. Most recently, researchers have found that postmenopausal women in the WHI who used HRT for a median of 5.6 years did not have an increased risk of cancer mortality during a cumulative follow-up of 18 years.[111]

PREVENTION

Avoidance of HRT may prevent drug-induced breast cancer, and available evidence suggests that the benefits of HRT should be carefully weighed against the increased breast cancer risk.[112] Patients at highest risk for breast cancer, especially those with a personal history of breast cancer and those with a strong family history, could use ET to relieve moderate-to-severe menopausal symptoms. Patients who take ET should also be informed of the increased risk of endometrial cancer.[112] In the Million Women Study cohort, women who discontinued use of HRT for at least 1 year had a breast cancer risk comparable to that of women who had never used HRT.[88]

American Cancer Society recommendations for lowering breast cancer risk for all women includes maintaining a consistent healthy weight, incorporating 150 minutes of moderate or 75 minutes of vigorous activity each week, and limiting or avoiding alcohol use. Breastfeeding for several months following delivery may also lower breast cancer risk.[113]

MANAGEMENT

Estrogen and progestin products should be discontinued in any patient diagnosed with breast cancer. Appropriate treatment of any malignancy depends on multiple factors at diagnosis, including stage, patient age, and the presence of comorbidities. Surgical excision with radiation therapy is an option for localized disease. Estrogen antagonists, such as tamoxifen, and aromatase inhibitors may be used depending on the hormone receptor status of the cancer. Chemotherapy, usually taxane- and/or anthracycline-based regimens with or without trastuzumab, are indicated for many patients. Radiation therapy is also commonly used in many cases.[114]

INFORMATION FOR PATIENTS

Patients who are receiving or are considering taking estrogens or combined estrogen and progestin products should be educated regarding the risks and benefits of these medications, including the increased risk of breast cancer with HRT. An increased risk of breast cancer has been observed with many HRT regimens, and it can be concluded that none is without risk.[88,90] It is best, therefore, to avoid HRT preparations altogether whenever possible.

ENDOMETRIAL CANCER

Endometrial cancer, also referred to as uterine carcinoma, is the most common malignancy of the female genital tract in the United States. More than 61,000 women are diagnosed with endometrial cancer annually and nearly 11,000 of those die from the disease.[13]

CAUSATIVE AGENTS

Hormonal therapy with estrogen and tamoxifen, an antiestrogen, has been implicated in the development of endometrial cancer (Table 57-1).

EPIDEMIOLOGY

Approximately 75% of women with endometrial cancer are postmenopausal with the median age of diagnosis of 62 years. A diagnosis of endometrial cancer before the age of 40 years is uncommon, accounting for about 5% of endometrial cancer cases.[115] Women who have used estrogen-only HRT are reported to have a relative risk of 2.7 for endometrial cancer as opposed to those never exposed, with 22.6 and 8 carcinomas per 10,000 person-years, respectively.[116] There is a linear association between duration of estrogen use and increased risk of endometrial cancer, with relative risk rising by 0.58 for each year of use. In addition, an elevated risk of endometrial cancer remains even 10 years after discontinuation of estrogen-only HRT.

Patients who receive tamoxifen for breast cancer are also at risk for endometrial cancer. Studies have found a relative risk approximately 2–3 times higher than the risk in an age-matched population. The rate of endometrial cancer occurrence among patients taking tamoxifen 20 mg/day was 1.6 per 1,000 patient-years, compared to 0.2 per 1,000 patient-years among those taking placebo. Even though endometrial cancer risk is higher in tamoxifen users, the benefits of breast cancer survival outweigh the small risk of endometrial cancer. A study extending tamoxifen use to 10 years reported similar outcomes in terms of improved breast cancer survival versus a small risk of endometrial cancer development.[117]

MECHANISMS

Estrogen causes hyperplasia of the endometrium, which, if unchecked, can develop into cancer (Table 57-2). Progestins inhibit this growth, likely explaining why combination estrogen and progestin HRT imparts a lower risk of endometrial cancer than estrogen-alone HRT.

Tamoxifen has antiestrogen effects in the breast, yet also has agonist activity on the endometrium via ERs. The agonist effect in the endometrium can result in benign endometrial proliferation, hyperplasia, polyp formation, invasive carcinoma, or uterine sarcoma.[118] Another proposed mechanism by which tamoxifen is carcinogenic relates to its ability to cause DNA damage. Tamoxifen is metabolized to several estrogenic metabolites and reactive intermediates. These reactive intermediates may form protein or DNA adducts to cause DNA damage. Therefore, tamoxifen may also cause malignancy by genotoxicity.[118]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Endometrial cancer can present as abnormal vaginal bleeding, dysuria, or pelvic pain (Table 57-3). Conditions to consider in the differential diagnosis include uterine fibroids, endometriosis, and pelvic inflammatory disease (Table 57-4). When endometrial cancer is suspected, a pelvic examination is typically the first diagnostic procedure performed. A Papanicolaou test might also be performed. The uterus can be imaged using transvaginal ultrasound, and the physician may perform a biopsy of the endometrial tissue.[119] In one case-control study, 40% of patients in whom endometrial cancer developed were diagnosed within 5 years of starting tamoxifen, 42% within 5–9 years of starting, and 18% after 10 or more years of treatment initiation.[120]

RISK FACTORS

Risk factors for drug-induced endometrial cancer are listed in Table 57-5. Longer duration of estrogen use is associated with increasing risk, with a relative risk of 1.4 after 1 year of use and 9.5 after 10 years of use as compared with those never treated with estrogen. Conjugated estrogens are associated with a higher risk of endometrial cancer than are synthetic estrogens, with relative risks of 2.5 and 1.3, respectively.[120]

Postmenopausal women with pre-existing abnormal endometrial pathologies may be more likely to have endometrial cancer after tamoxifen therapy than patients without these pathologies. The American College of Obstetricians and Gynecologists (ACOG) review of tamoxifen-induced endometrial cancer cases concluded that etiology may be both dose- and duration-dependent.[121] There are reports that patients who use tamoxifen at a higher dose (40 mg/day) are more likely to develop more aggressive tumors. There are two sets of data regarding duration of tamoxifen use in breast cancer patients: data for patients with 5 years of tamoxifen use and data for 10 years of tamoxifen use in postmenopausal women. Five years of adjuvant tamoxifen use produces an absolute 15-year endometrial cancer risk of about 2–3% and use for 10 years produces an additional risk by year 15 of about 2%.[117,122,123]

MORBIDITY AND MORTALITY

In general, the overall survival rates for endometrial cancer are favorable if diagnosed during an early stage (0–II). Overall 5-year survival decreases significantly in women diagnosed with stage III or IV disease. According to the American Cancer Society, the 5-year survival rates for stage III range from 47% to 58% and stage IV from 15% to17%.[124]

A review of three large case-control studies of tamoxifen-induced endometrial cancer (after 5 years of adjuvant therapy) revealed less favorable morphological subtypes of endometrial cancer than found in other populations and thus a relatively poor prognosis.[125] The 3-year survival in tamoxifen-induced endometrial cancer patients is 75% versus 94% in the general population. A large case-control study of endometrial cancer following tamoxifen use for breast cancer found that stage III and IV endometrial cancers occurred more frequently in long-term tamoxifen users than nonusers. The study also found that long-term users experienced significantly higher risk of developing malignant mixed mesodermal or sarcomas of the endometrium than those not taking tamoxifen (15.4% versus 2.9%; $P < 0.2$).[126]

PREVENTION

Multiple studies have demonstrated that women taking progestin with estrogen for at least 10 days per month do not have an elevated risk of endometrial cancer (Table 57-6).[120,127-129] Progestins counteract the proliferative effects of estrogen on endometrial tissue. However, combined estrogen–progestin HRT increases the risk of breast cancer, as previously described. Therefore, the risks and benefits of estrogen-only versus combination HRT must be carefully considered before either is used.

Avoiding the use of tamoxifen is the best method to prevent drug-induced endometrial cancer. Substitution of raloxifene can be considered in patients for whom tamoxifen is utilized as chemoprevention. Raloxifene is a selective ER modulator similar to tamoxifen; however, it does not exert the same degree of agonist effects on the uterus as tamoxifen. The Study of Tamoxifen and Raloxifene trial demonstrated raloxifene as a drug of choice for reducing the risk of breast cancer among postmenopausal women because of a better adverse event profile compared to tamoxifen.[130] Tamoxifen has been shown to be highly effective in treatment of ER+ breast cancer. The benefits and risks of its use must be weighed carefully on a case-by-case basis. Some studies suggest that the aromatase inhibitors may have efficacy in the treatment of ER+ breast cancer comparable to that of tamoxifen but without the risk of secondary endometrial cancer. Following discontinuation of tamoxifen, patients continue to have an increased risk of endometrial cancer for at least 5 years.[122]

MANAGEMENT

Endometrial cancer is primarily treated surgically with hysterectomy and bilateral salpingo-oophorectomy. Pelvic radiation or vaginal brachytherapy are adjuvant treatment options, depending on the stage of the disease. For more advanced stages of endometrial cancer, chemotherapy may be used. The NCCN provides the most up-to-date guidelines on the management of endometrial cancer.[114]

INFORMATION FOR PATIENTS

In 2014 the ACOG provided specific recommendations regarding the use of tamoxifen and the development of endometrial cancer. The guidance was in response to new data demonstrating benefit with tamoxifen use extended to 10 years in breast cancer. Recommendations include informing women about the risks of endometrial changes such as proliferation, endometrial hyperplasia, endometrial malignancy, and uterine sarcoma. Women should be advised to promptly report any abnormal vaginal bleeding, bloody vaginal discharge, or spotting. In addition, postmenopausal women taking tamoxifen should be closely monitored for symptoms of endometrial cancer or hyperplasia. Premenopausal women treated with tamoxifen have no increased risk of endometrial cancer and, therefore, require no additional monitoring beyond routine gynecologic care.[117]

Women taking estrogens should also be informed of their increased risk of endometrial cancer. If a decision is made to use one of the drugs known to increase the risk of endometrial cancer, patients should be advised to seek immediate medical attention if they experience symptoms of endometrial carcinoma. Patients should also understand the importance of undergoing an annual gynecologic examination.

BLADDER CANCER

According to the American Cancer Society, nearly 82,000 people in the United States are diagnosed with bladder cancer annually and approximately 17,000 of these will succumb to the disease. The median age of diagnosis is 65 years, and the disease is rarely diagnosed in individuals younger than 40 years of age. Currently, no established methods exist for screening or prevention.[131,132]

CAUSATIVE AGENTS

Cyclophosphamide has long been known to cause cancer of the bladder when used to treat malignant or nonmalignant conditions (Table 57-1). Another agent with links to bladder cancer is pioglitazone (an oral antidiabetic agent in the thiazolidinedione class). Although a link between pioglitazone and bladder cancer was not identified when the drug was approved in 1999, accumulating postmarketing evidence has led to an update in the package insert to reflect this cancer risk.[132,133]

EPIDEMIOLOGY

Risk for bladder cancer after cyclophosphamide use varies with cumulative drug dose.[134] NHL patients receiving 20–49 g of cyclophosphamide have a sixfold increased risk of bladder cancer; those receiving 50 g or more have a 14.5-fold increased risk as compared with controls.[135] In the noncancer setting, the absolute risk of bladder cancer in a cohort of patients treated with cyclophosphamide for granulomatosis with polyangiitis, formerly known as Wegener granulomatosis, was found to be 10% at 16 years after diagnosis.[136]

Postmarketing observational studies have suggested a link between long-term use (>24 months) of pioglitazone and the development of bladder cancer. One retrospective cohort from the French health insurance database demonstrated increased risk of bladder cancer (overall HR 1.22, 95% CI 1.05–1.43; exposure >24 months 1.34, 95% CI 1.04–1.79), which led to the suspension of pioglitazone use France in June 2011.[137,138] In 2003, the manufacturer and the FDA agreed to a 10-year observational study to evaluate the risk of bladder cancer with pioglitazone in diabetic patients. The 5-year interim analysis found that patients who received pioglitazone for longer than 24 months had a small but statistically significant elevated risk of bladder cancer (HR 1.4, 95% CI 1.0–2.0), a finding that has been confirmed in most, but not all, other studies. One study found patients who received pioglitazone for <24 months did not experience an increased risk and these authors concluded there was no statistically significant association between pioglitazone and bladder cancer.[139] However, in a study of 145,806 newly diagnosed diabetic patients treated with antidiabetic drugs and followed for 14 years, pioglitazone was associated with a 63% increased risk of bladder cancer. Rosiglitazone was not associated with increased risk, suggesting bladder cancer is drug-specific and not a class effect.[140] Pioglitazone is still available in the United States, and the package insert includes a warning regarding bladder cancer risk.[133,141]

MECHANISMS

Two metabolites of cyclophosphamide, acrolein and phosphoramide mustard, are thought to cause bladder cancer (Table 57-2). Both metabolites form DNA adducts, which can lead to mutation and subsequent carcinomatosis. Acrolein has been shown to cause urinary bladder papilloma formation in both animals and humans.[134] In one series, many samples of human bladder tumor tissue were found to contain mutations of tumor-suppressor gene *p53* that were consistent with known phosphoramide mustard–induced changes.[142]

The mechanism by which pioglitazone may induce bladder tumors has not been fully elucidated. One potential mechanism has been described from animal studies and involves the agonist nature of pioglitazone on the peroxisome proliferator-activated receptors (PPARs) found on urothelial cells. In theory, this direct agonist activity may be the cause of bladder carcinogenesis.[143,144]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Symptoms of bladder cancer are very nonspecific and include hematuria and dysuria (Table 57-3). In patients with more advanced bladder cancer, upper obstruction or pain may also occur.[132]

RISK FACTORS

Higher cumulative doses of cyclophosphamide (both oral and intravenous), especially doses >20 g, place a patient at increased risk for bladder cancer (Table 57-5). In addition to dose-dependent risk, some literature suggests that antecedent hemorrhagic cystitis may be associated with a future increased risk of bladder cancer.[134] Cigarette smoking and aromatic amine exposure (from the manufacture of certain plastics, dyes, or pesticides) are additional risk factors for cancer of the bladder.[145] Pioglitazone use over 24 months has also been linked with increased risk of bladder cancer.[139,141]

MORBIDITY AND MORTALITY

Specific mortality rates from cyclophosphamide-induced bladder cancer have not been reported. In general, the 5-year survival rate for those diagnosed with local disease is good compared with those diagnosed with advanced disease. The 5-year survival rate for local disease is 70% versus 8% for advanced disease.[131]

PREVENTION

Methods to prevent cyclophosphamide-induced bladder cancer are presented in Table 57-6. Mesna, a drug commonly given in combination with high-dose cyclophosphamide to prevent hemorrhagic cystitis, has been associated with a reduction in the incidence of cyclophosphamide-induced bladder tumors in rats, although this effect has not been proven in humans.[146] There are no published data regarding the effect of mesna on the rate of secondary bladder cancer in patients so the use of mesna for this indication has not been established.[134]

Avoiding the use of cyclophosphamide may be the best preventive strategy when alternative therapies are available. When the drug must be given, using a cumulative dose of <20 g is desirable because this amount may not be associated with an increased relative risk of bladder cancer.[134,136] Patients who require prolonged treatment and cumulative doses of >20 g of cyclophosphamide could theoretically benefit from the concurrent administration of mesna, although, as noted, conclusive evidence is lacking.

Some literature suggests the risk of bladder cancer may increase with pioglitazone therapy lasting longer than 24 months. Therefore, prevention strategies would include avoiding the use of this medication or avoiding its use for >24 months.[133] Over the past decade several new agents have been approved for the management of type 2 diabetes mellitus. Therefore, pioglitazone avoidance is a reasonable option for healthcare professionals concerned with pioglitazone-associated bladder cancer.

MANAGEMENT

Transurethral tumor resection can be used for patients with localized bladder cancer. When the musculature of the bladder is involved, radical cystectomy is a common treatment. Patients may receive intravesical therapy with Bacillus Calmette-Guerin or intravesical chemotherapy in the adjuvant setting. Depending on the depth of invasion, neoadjuvant chemotherapy can be considered. Concomitant radiotherapy may also be used in select patients. The NCCN provides the most up-to-date guidelines for health professionals on the management of bladder cancer.[132]

INFORMATION FOR PATIENTS

Patients who receive cyclophosphamide or pioglitazone should be warned about the increased risk of bladder cancer. They should be advised to immediately report abnormal urinary symptoms, including hematuria and dysuria. Although there are no specific recommendations for bladder cancer screening, it may be reasonable to screen patients receiving long-term cyclophosphamide therapy using urinalysis and urine cytology.

CHAPTER 58

Teratogenicity

Kylie N. Barnes

Teratogenic exposure is defined as exposure to an exogenous agent that can modify normal embryonic or fetal functional or structural development.[1] An exposure to a substance may increase risk; however, some exposures may have no impact at all. When evaluating the risk of drug-induced teratogenicity, it is important to consider exposure level, which includes the dose of the drug and the extent to which a patient may be concomitantly exposed to other substances associated with the same developmental risks. For example, a pregnant woman who is a cigarette smoker (known to be associated with low birth weight) exposed to a drug known to increase the risk for low birth weight is at greater risk of having a low birth weight infant born as a result of the exposure to two teratogens.[2] Although teratogenic exposure is often associated principally with an increased risk of major congenital anomalies (defects incompatible with life or requiring major corrective surgery), they are also associated with an increased risk for adverse pregnancy outcomes, including spontaneous abortion, stillbirth, minor structural anomalies (e.g., ear tags, extra digits, bent or curved fingers known as clinodactyly), preterm birth, intrauterine growth restrictions (IUGRs), and behavioral or cognitive deficits.

Some prescription and over-the-counter medications can be teratogenic. Additionally, recreational drugs, alcohol, nicotine, some chemicals, maternal infections and conditions during pregnancy, chromosomal disorders, and heredity may also have a negative impact on fetal development.[2-7] Due to ethical concerns, clinical studies specifically evaluating drug-induced teratogenicity in humans are lacking, and information regarding patients' direct exposure to medications during pregnancy can be limited.

For many medications, information regarding effects on pregnancy and the developing fetus are based on experimental animal studies and human data are unavailable. Animal data can be useful in indicating potential adverse effects; however, interpretation of this information requires an understanding of the differences in pharmacokinetics of the drug in the animal model and in humans, and that information is not always available. Although case reports of adverse effects of medications administered during pregnancy are available in the medical literature and/or through U.S. Food and Drug Administration (FDA) surveillance documents, these reports often lack critical information regarding concomitant exposure to other potential teratogens and potential environmental exposures. As a result, causality assessment is often very difficult. In 1965, a list of criteria for causation was published that focuses on the strength of association, consistency of the association, specificity, temporal relationship, coherence, biologic gradient, biologic plausibility, experimentation and analogy assessing other cause-effect relationships. This list for causation is often used as a baseline for practitioners to help assess teratogenic causality.[8] All criteria do not have to be met to consider an association as causal; however, the more criteria met, the greater the odds of causal relationship. In all cases, it is also important to take into consideration maternal physiological changes and their impact on drug metabolism, the fetal developmental stage at the time of proposed drug exposure, and the impact confounding variables may have on the fetus.

Retrospective and prospective data are also available from pregnancy registries that collect information regarding exposure to specific drugs or groups of drugs. Typically these registries monitor for major birth defects and can be good sources of early information regarding a new drug. Although sample size in these registries is often insufficient to prove an association between a suspect drug and a teratogenic effect, trends may be identified.

Case-controlled studies that retrospectively evaluate a specific outcome or a particular birth defect are available for some medications, and these often allow for collection of information about potential confounding variables (e.g., age; socioeconomic status; use of alcohol, tobacco, and/or illicit drugs). A major limitation in case-controlled studies is recall bias wherein women who have a negative pregnancy outcome are more likely to recall details of their pregnancy and exposures than those who had a normal outcome. It is also difficult to evaluate an agent for increased risk retrospectively, when the full pattern of the anomaly is not well understood.

Because specific, unambiguous data regarding a medication's potential for teratogenicity are not always available, evaluating the risk versus benefit of using a given drug to treat a specific condition in a given patient can constitute a significant challenge for clinicians.

HISTORY AND REVIEW OF TERATOGENICITY

Prior to the 1940s, it was generally believed the placenta provided a protective barrier for the developing embryo and fetus. Naively, clinicians believed that mothers could be exposed to agents and they would not impact normal gestational development. An Australian ophthalmologist, Norman Gregg, first raised the idea that exposure to an agent during pregnancy could cause harm to the developing fetus after he noticed an increasing number of children diagnosed with congenital cataracts shortly after a rubella epidemic. His findings led to further investigations that identified additional developmental abnormalities associated with fetal rubella infection, including congenital heart defects, hearing deficits, poor growth, and thrombocytopenia.[9]

During the early 1960s, an Australian obstetrician and a German geneticist together observed that first trimester maternal use of thalidomide, a sedative-hypnotic agent, was associated with the appearance of a characteristic pattern of limb reduction anomalies and other defects.[10,11] Thalidomide had undergone testing in rodents during product development and had not shown any effect on limbs. Early studies were not well conducted, however, and later work revealed intravenous administration of thalidomide in rats produced skeletal abnormalities involving the ribs, vertebra, hips, and tail.[12] Additional studies in rabbits showed an increased sensitivity to thalidomide embryo toxicity as compared to rats, a difference that was determined to be due to pharmacokinetic variation between the species.[12] As a result of slow detection of risk, many babies were born with severe deformities of the arms and legs, as well as other life-altering malformations. This finding led to the realization that therapeutic agents could induce malformations and cause harm. New concerns regarding other drugs and potential for harm began surfacing.

Today, many obstetricians and other healthcare providers instruct patients to avoid exposure to all medications during pregnancy due to concerns for potential harm to the developing fetus. Despite this advice, drug use during pregnancy is fairly common. Studies have shown that approximately 70% of women use at least one prescription medication during their pregnancy and over 90% use at least one prescription or an over-the-counter medication.[13] In many cases, these medications are essential for the health of the mother or fetus; however, in other cases, the exposure could be avoided.

Roughly 50% of women of reproductive age rely on the Internet for their health information, and they are more likely to share prescription medications with and/or borrow prescription medications from others. These factors increase concern regarding medication exposure during pregnancy—especially exposure that may occur before the pregnancy is known.[14]

In this chapter, we focus on mechanisms of placental drug transfer and the drugs known to cause major fetal structural or functional abnormalities. Birth defects that are due to other causes (e.g., hereditary, chromosomal deficits, maternal illness, or chronic conditions) will be noted when known to have a significant impact on fetal development.

MECHANISMS OF PLACENTAL TRANSFER

Classification of mammalian placentas is based on the number of layers between maternal and fetal blood; the layers include the hemochorial (rat, rabbit, guinea pig), endotheliochorial (cat, dog), and epitheliochorial (sheep, pig, horse).[15] Human placentas are of the hemochorial type in which fetal tissue is in direct contact with maternal blood.[15] The different structural types of the various mammalian placentas affects their function, including the transfer and metabolism of drugs. Variation makes it difficult to utilize data from animal studies to predict how a human fetus might respond to maternal drug exposure. This variability also helps explain why data may show no fetal impact of drug exposure during pregnancy in one species but significant impact in others.

The human placenta begins forming during early pregnancy at the point of implantation, just shortly after conception, and immediately helps with general nutrient exchange between the mother and fetus. By the end of the first trimester, the placental circulation has fully developed, and the placenta separates the blood supplies from the mother and the fetus.[16] The placenta receives its own blood supply and perfusion by both the mother and fetal circulations. The main purpose of the placenta is to provide nourishment and oxygen to the fetus. Many nutrients, including glucose, amino acids, and vitamins are delivered through the placenta from the mother to the fetus through specific transport mechanisms. The placenta also helps facilitate the removal of metabolic waste products from fetal blood, delivering the waste to the maternal circulation for removal. The placenta undergoes significant change throughout pregnancy. As pregnancy progresses, the placenta thins and increases in surface area to keep up with the nutritional and energy demands of the growing fetus. At 28 weeks gestation, the average placental exchange area is 3.4 m^2 and increases to an impressive 12.6 m^2 by term. The diffusion distance is also impacted throughout the pregnancy, starting at 50–100 micrometers around 8 weeks, decreasing to 4–5 micrometers at pregnancy term.[16]

Almost all drugs the mother takes during pregnancy will enter into fetal circulation via passive diffusion through the placenta, although the extent varies. Additionally, there are active transporters on both the fetal and maternal side of the placenta that actively pump some drugs across the placenta.[17] The extent of placental transfer depends on the molecular weight of the drug, the extent of drug binding to the plasma protein, and the overall lipophilicity of the drug. Most drugs with a molecular weight <600 Da cross the placenta, while drugs >1,000 Da cross very poorly (e.g., heparin, insulin).[16] Of note, larger drugs (e.g., monoclonal antibodies) pass through the placenta through active transport in a linear fashion, with minimal transport occurring during the first trimester and maximum transport occurring during the third trimester.[18] Drugs whose molecular weights fall between 500 and 1,000 Da typically have incomplete transfer across the placenta, and the amount of drug transfer can vary.[16]

Nonionized drugs have a tendency to cross the placenta more readily than ionized drugs. Fetal blood often has a lower pH than maternal blood. Hydrogen ions bind to the nonionized form of the drug leading to ion trapping and resulting in higher drug concentrations in the fetal blood. This becomes particularly important with the local anesthetics, which are mostly weak bases. Fetal acidosis produces higher fetal drug concentrations because of binding of hydrogen ions to nonionized forms of the drug, leading to trapping of the local anesthetic in fetal circulation.

In general, highly lipophilic drugs have increased placental transfer. However, extreme lipophilicity may actually impede transfer as highly lipophilic substances may accumulate in the placenta. In these cases, the drug is absorbed by placental tissue, where it is stored, and it is not readily released into fetal circulation.

FACTORS AFFECTING TERATOGENICITY

Factors to consider when evaluating patients and drugs for teratogenicity risk include maternal physiologic changes that can impact drug levels throughout pregnancy, fetal susceptibility to the drug based on the developmental stage at the time of exposure, and the anticipated exposure level (the dose of the drug and the extent to which the patient may be concomitantly exposed to other substances associated with the same developmental risks).

Throughout pregnancy, a woman's body undergoes many changes, including physiological changes that can impact drug metabolism and clearance. These changes can also influence medication dosing, requiring in some cases larger doses than typically seen in the nonpregnant population.

The impact of drug exposure on a developing fetus is highly dependent on the timing of exposure. The term *gestational timing* is often used to describe the timeframe within which an exposure must occur to have an impact on fetal development. For example, the critical window for an agent to interfere with the closure of the neural tube during fetal embryology is between days 21 and 28 after conception.[19] For a drug to induce an increased risk of neural tube defects, the mother must take it prior to the second month of pregnancy. If the mother does not start taking the drug until later in pregnancy, the critical window has passed, and development of a neural tube defect would not be due to exposure to the drug. Drugs can have a different impact on development throughout different stages of pregnancy as well. For example, when warfarin is taken by a mother during the first 6–9 weeks of pregnancy, there is an increased pattern of nasal hypoplasia and skeletal abnormalities.[1] However, when warfarin is taken later in pregnancy, an increased risk in central nervous system (CNS) abnormalities is observed. The increased risk of nasal hypoplasia and skeletal abnormalities is likely due to vitamin K deficiency, whereas the CNS abnormalities are due directly to complications from fetal bleeding when warfarin is used during the second and third trimesters.[20] Interestingly, exposure during the first 2–4 weeks after conception poses little risk for harm. Early embryonic cells are able to replace themselves if there is damage due to exposure to a causative agent. If the magnitude of cell loss or damage is too great, however, spontaneous abortion can result.[21]

Congenital anomalies are defined as abnormalities that are present at birth, although they may be diagnosed in utero, at the time of birth, or months or years after the child is born. In the United States, birth defects occur in 1 of every 33 babies each year (3%), affecting an estimated 120,000 babies annually. Birth defects are also the leading cause of infant deaths, accounting for 20% of all infant deaths.[22] Typically, the anomalies are structural in nature; however, they may not always be inherently visible, as in mental retardation. Often birth defects are present at the time of conception and are due to genetic or chromosomal abnormalities as, for example, with Down syndrome. However they can also develop as a result of exposures or disruptions during the embryonic period or early fetal period, as with spina bifida, or result from exposures throughout gestation due to maternal pre-existing conditions (e.g., diabetes, hypertension, and psychological disorders), environmental exposures, and drug exposures. Defects can vary from a minor to a major anomaly.

CONDITIONS ASSOCIATED WITH TERATOGENICITY

LEARNING DISABILITIES

Learning disabilities are conditions characterized by an inconsistency between potential and actual levels of intellectual ability. They can involve disabilities or impairments in physical, learning, language, or behavior areas and include issues with concentration, attention, language development, or visual and aural information processing. For children with learning disabilities, struggles can include the ability to use or understand spoken or written language, complete math problems, coordinate movements, or focus their attention on specific tasks. They typically begin during the developmental period and usually persist throughout life.[23]

CAUSATIVE AGENTS

Learning disabilities can either be congenital or acquired; however, no single cause has been identified. Prenatal exposure to anticonvulsant drugs, specifically valproic acid monotherapy, has been associated with reduced cognitive ability, autistic spectrum disorders including childhood autism, Asperger syndrome, atypical autism, and additional educational needs in exposed children.[24-26] A recent prospective observational study evaluated 224 children exposed to anticonvulsant drugs during the prenatal period for 6 years of follow-up and found children exposed to valproic acid did poorly on measures of verbal and memory abilities and had lower IQs at age 6 when compared to children exposed to other anticonvulsant agents.[26] Phenytoin exposure has been associated with mental deficiency and an average IQ score 10 points lower in children when compared to children not exposed to phenytoin.[27,28] Additionally, some studies have suggested risk for developmental delay after prenatal exposure to carbamazepine; however, other studies have not confirmed this finding.[26,29,30]

EPIDEMIOLOGY

Recent data estimate 8–10% of American children under 18 years of age have some type of learning disability.[31] The incidence of drug-induced learning disabilities is unknown.

MECHANISMS

The cause(s) of learning disabilities is not known. Possible causes include heredity, teratogenicity, problems during pregnancy and birth (e.g., lack of oxygen, premature labor), or incidents after birth (e.g., head injury, nutritional deprivation). One theory suggests that learning disabilities occur as a result of small disturbances in brain development in areas dealing with language.[32] The effects of antiepileptic drugs on cognition and neurological development are not well known; however, animal studies have shown that in utero exposure can induce both anatomical and behavioral anomalies. The exact mechanism for the behavioral anomalies is not known, although evidence suggests the mechanism is multifactorial and results from folate deficiency, ischemia, neuronal suppression, detrimental effects of reactive intermediates, and antiepileptic drug-induced neuronal apoptosis leading to dysfunction in remaining neurons.[33] It is important to note that learning disabilities are not caused by economic disadvantage, environmental factors, or cultural differences.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Learning disabilities include a spectrum of disorders that affect the way the brain is able to process information and can vary greatly in severity. Children with learning disabilities usually have average or above average intelligence but struggle with some aspects of learning. Identifying letters of the alphabet may be an easy task for the child, but putting the letters together to read may become confusing and difficult. Children with learning disabilities may present as frustrated, angry, or depressed and may have poor self-image due to struggles accomplishing tasks they see their peers mastering with little difficulty.

Learning disabilities are usually discovered during the first years of elementary school as the child is beginning to learn to read and write. To obtain a diagnosis, a specialist must formally evaluate the child at 5–7 years of age, and then the tests are repeated as the child gets older. If problems are noticed or suspected at younger ages, testing is usually delayed because learning styles and speed varies greatly during the early years of childhood development, and results are often inconclusive.

RISK FACTORS

Maternal social history is important, as smoking, alcohol, and cocaine exposure in utero have been linked to developmental delays in children. Additionally, other factors in an infant’s environment including poor nutrition and exposure to toxins such as lead in water or paint can increase risk for development of a learning disability.[34]

MORBIDITY AND MORTALITY

Learning disabilities can be an isolated learning problem with little impact on a child’s life or can occur as several overlapping learning disabilities that have lasting implications and are lifelong conditions. The extent of impact a learning disability can have depends on the learning disability itself, when it is detected, and the resources available for help. Children born with a learning disability may require a variety of treatments throughout life to manage that disability. The most common treatment for learning disabilities is special education. Once a learning disability is suspected, trained educators will perform diagnostic testing and evaluations to assess the child’s academic and intellectual performance and potential. The exact approach for treatment will vary per child, but is centered on teaching learning skills by building on abilities and strengths, while compensating for disabilities and weaknesses. Depending on the child's limitations, other health professionals such as speech and language therapists may be added to the care team. If the child struggles with attention and/or concentration, behavioral therapy and pharmacotherapy may be added.[35]

LOW BIRTH WEIGHT

Low birth weight is defined as an infant born weighing <2,500 grams, or 5.5 pounds, and can occur because an infant is born too small, too early, or a combination of both. An infant's weight at birth often correlates closely with their gestational age and is a good predictor of both short- and long-term outcomes.[36] When an infant is born smaller than the usual size for a baby born at the same number of weeks gestation, the term *small for gestational age* is used. Small for gestational age babies have birth weights below the 10th percentile when compared to babies of the same gestational age.[37] Additionally, small for gestational age babies may be born premature, at term, or post-term and may be equally small all over, or be of normal length, but lower in body weight and mass. When compared to infants born at a normal weight, low birth weight infants carry a higher risk for many health problems, are at higher risk of developing infections, and may potentially suffer from delayed motor and social development or learning disabilities.

CAUSATIVE AGENTS

Maternal exposure to phenytoin, corticosteroids, and warfarin have been linked to lower birth weights in infants.[38-40] Calcium-channel blockers, angiotensin-converting enzyme inhibitors, and beta-adrenergic receptor blockers have been associated with IUGR leading to infant lower birth weight; however, it is difficult to determine whether the increased risk is due to the medication exposure or the underlying disease state.[41-48]

EPIDEMIOLOGY

In 2014, the overall incidence of low birth weight in infants in the United States was 8% (318,847 out of 3,988,076 registered live births, or roughly 1 in 12).[49] The overall incidence of drug-induced low birth weight or small for gestational age births is unknown, but it is likely very low. An estimated 70% of low birth weight babies are born prematurely, or prior to 37 weeks gestation.[49] One-fourth to one-third of infants born with a low birth weight are found to have sustained IUGR.[50]

IUGR affects 3–9% of pregnancies and is the leading cause of perinatal mortality and morbidity.[51]

Maternal corticosteroid use has been associated in some studies with lowering birth weight, but recent literature indicates impact may be minimal after one or two short courses of therapy.[38,52] A randomized trial evaluating the impact of a single rescue antenatal steroid course compared to placebo in 113 cases showed no difference in birth weight.[53] In a study evaluating single versus repeat courses of antenatal corticosteroid courses in pregnant patients, repeat dosing was associated with decreased birth weight below the 10th percentile when compared to a single course ($p = 0.048$), causing the data and safety monitoring committee to stop the trial early.[39]

Calcium-channel blockers and beta-adrenergic blockers have both been associated with intrauterine IUGR and low birth weight. It can be difficult to determine true causality because chronic hypertension has also been linked to IUGR, low birth weight, and premature birth.[40] Calcium-channel blockers, specifically nifedipine, have been associated with changes in infant birth weight. However, in a study of 145 pregnant women receiving nifedipine or placebo, there was no significant difference between the two groups in the percentage of infants weighing less than the 10th percentile (OR 0.8, 95% CI 0.4–1.4) or in the mean birth weight.[41] Similarly, beta-blockers, in particular atenolol, have been linked to fetal growth restriction when taken in early pregnancy.[42] A retrospective study of 78 pregnancies exposed to atenolol showed atenolol use associated with fetal growth restrictions, specifically when used in early pregnancy and continued through delivery.[43] Another randomized trial evaluated atenolol 100 mg daily compared to placebo when given prior to 24 weeks gestation in normotensive women with high cardiac output to help prevent development of pre-eclampsia. The results were similar, with infants exposed to atenolol weighing 440 g less than infants in the placebo group ($p = 0.02$).[44] The smallest infants were born to mothers treated with atenolol who also experienced the largest reductions in cardiac output. An additional retrospective study evaluating 158 pregnancies in women with cardiovascular disease found a significant difference in the incidence of fetal growth restrictions between beta-blockers and placebo ($p < 0.05$). The beta-blocker group included propranolol, metoprolol, atenolol, and bisoprolol, and the incidence of fetal growth restriction varied depending on the agent used (35%, 17%, 33%, and 0%, respectively).[45]

Conversely, a recent meta-analysis (7 studies of 802 women) evaluating use of antihypertensive medications, including beta-blockers, calcium-channel blockers, and others, for chronic hypertension in pregnancy showed no difference in birth weight (weighted mean difference 60 g, 95% CI 200–80 g).[47] A common theme raised by many authors is that fetal growth changes are likely impacted by many factors other than just maternal blood pressure. Before initiating therapy for hypertension, it is important to consider the mother's starting blood pressure, timing of gestation relative to the start of drug therapy, and the treatment goal.[54]

MECHANISMS

The two most common reasons for low birth weight are premature birth and IUGR.[55] Understandably, babies born prior to full term are at greater risk for lower birth weight. Growth-restricted babies, on the other hand, may have a lower birth weight for a number of reasons. Some growth-restricted babies may be small simply because their parents are small. Others may have a lower birth weight because something stopped or slowed their growth during development. The cause of IUGR is not always known, but risk factors have been identified. Maternal hypertension, for example, can cause the small blood vessels in the placenta to tighten, allowing less blood and nutrients to cross to the baby. This can potentially cause delayed or restricted growth for the developing fetus.[56]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

As defined above, low birth weight infants are those born weighing <2,500 grams, or 5.5 pounds. Infants born small for gestational age have birth weights below the 10th percentile when compared to other babies of the same gestational age. A careful exposure history is necessary to determine whether or not drugs were the likely or possible cause of low birth weight. Other causes may be ruled in or out based on the timing of delivery, the mother's health status, and/or other conditions present at birth.

RISK FACTORS

Risks factors for drug-induced low birth weight include exposure to known causative agents during pregnancy; however, the exact cause of low birth weight, or fetal growth restriction, is not always known. Chromosomal disorders, such as trisomy 21, have also been linked to an increased risk of low birth weight. Additionally, several maternal conditions have also been linked to an increased risk, including hyperthyroidism and hypertension, maternal infections during pregnancy, including cytomegalovirus, rubella, chickenpox, and toxoplasmosis, lack of weight gain for the mother during pregnancy, a previous preterm birth, maternal age <15 or >35, and social and economic factors (low income, low educational status, stress, domestic violence or abuse, and unmarried status).[49,57,58]

Maternal cigarette smoking has also been associated with a decrease in infant birth weight of approximately 135–300 g.[59,60] Interestingly, when smoking cessation can occur prior to the third trimester, the effect on decreased birth weight is reduced.[61] A reduction in birth weight is also associated with maternal alcohol consumption, even in amounts as little as 2 drinks per day.[62] Use of cocaine has been associated with a restriction in growth leading to lower birth weights and to a reduction in head circumference.[63]

MORBIDITY AND MORTALITY

Birth weight is an indicator of fetal growth, and low birth weight predicts short-term survival in newborns more reliably than any other characteristic. Small body size at birth is also an important predictor of long-term health. The incidence of morbidity, hospitalizations, or death associated with drug-induced low birth weight in infants is more difficult to determine.[64] Research has shown an estimated 1.1 million babies die annually from complications of preterm birth.[65] Additionally, low birth weight increases the infant's risk of developing diabetes and cardiovascular diseases later in life.[66,67] Many cohort studies have demonstrated an inverse relationship between birth weight and adult morbidity and mortality from cardiovascular diseases.[66] However, available data do not consider environmental factors, social factors, or genetic factors that may contribute to fetal development.

OROFACIAL CLEFTS

Cleft lip and cleft palate are birth defects that occur when a baby's lip or mouth does not form properly during fetal development. Together, these anomalies are commonly referred to as orofacial clefts. The lip forms between weeks 4 and 7 of pregnancy, as tissue and cells from each side of the head grow together to form the face. A cleft lip occurs when the tissue that forms the lip does not completely join together before birth. As a result, the lip remains open and appears split (**Figure 58-1**). The opening can be a small slit along the lip line or can be a large opening that extends up into the nose. The palate forms between weeks 6 and 9 of pregnancy, as tissues form together to make the roof of the mouth. A cleft palate occurs when there is a disruption in the joining of the tissues, resulting in an opening of the palate. The extent of the opening can vary, with the front and back of the palate remaining open, or only a small part of the palate remaining open (**Figure 58-2**).

CAUSATIVE AGENTS

Several medications have been linked to orofacial cleft development when used in early pregnancy. Prenatal exposure to drugs, including phenytoin, primidone, carbamazepine, oxcarbazepine, phenobarbital, ethosuximide, valproic acid, topiramate, lamotrigine, mycophenolate, isotretinoin, corticosteroids (topically and systemically), benzodiazepines, and beta-2 agonists, have been associated with an increased risk of orofacial cleft.[68-74]

EPIDEMIOLOGY

It is estimated that about 2,650 babies are born with a cleft palate and 4,440 babies are born with a cleft lip with or without a cleft palate every year in the United States (a total of about 1 in 600 babies).[75] The overall incidence of drug-induced orofacial clefts is unknown. The incidence of orofacial clefts associated with use of specific agents during pregnancy, where known, is discussed in further detail below.

A large meta-analysis designed to compare safety during pregnancy evaluated 96 studies involving 58,461 patients exposed to antiepileptic medications during pregnancy, including ethosuximide, primidone, topiramate, phenobarbital, phenytoin, carbamazepine, oxcarbazepine, gabapentin, and levetiracetam used as monotherapy and in combination therapy. The following monotherapies were associated with significantly more cases of cleft lip and/or cleft palate when compared to control: ethosuximide (OR 22.22, 95% CI 4.56–87.64), primidone (OR 7.68, 95% CI 1.41–29.27), topiramate (OR 6.12, 95% CI 1.89–19.05), phenobarbital (OR 5.75, 95% CI 2.41–14.08), phenytoin (OR 3.11, 95% CI 1.31–7.72), and valproic acid (OR 3.26, 95% CI 1.38–5.58). Additionally, the following combination therapies were associated with significantly more cases of cleft lip and/or cleft palate when compared to control: phenobarbital, phenytoin and primidone (OR 11.5, 95% CI 1.70–63.48), phenytoin and primodone (OR 16.75, 95% CI 3.02–77.19), carbamazepine and phenobarbital (OR 18.51, 95% CI 3.34–94.21), and carbamazepine and valproic acid (OR 19.12, 95% CI 3.74–88.68).[72]

A large study evaluated 4,459 cases of valproic acid exposure during pregnancy and identified 50 cases of orofacial cleft. Thirteen cases occurred in 1,282 valproic acid monotherapy-exposed pregnancies. Nine of those patients experienced isolated cleft palate, and four developed cleft lip and cleft palate, representing an 11.3-fold and 3.5-fold increase risk for isolated cleft palate and cleft lip and palate, respectively.[76]

Maternal lamotrigine use has also been associated with an increase in cleft palate development, with rates ranging between 2% and 5.6%.[77] A review of 684 women taking lamotrigine as monotherapy during pregnancy found that 16 of the infants had a major malformation. Of those, five had oral clefts (7.3 per 1,000) with three cases of isolated cleft palate, one case of isolated cleft lip, and one case of cleft lip and palate. This represents a 10.4-fold increase (95% CI 4.3–24.9) in isolated left palate development when compared to 206,224 unexposed infants surveyed at birth.[78] However, most studies have demonstrated much lower risks. One study conducted in the United Kingdom reported only one infant (0.1%) with cleft palate identified among 1,151 mothers exposed to lamotrigine.[79] In another study, only one infant was born with oral cleft among 1,558 lamotrigine-exposed mothers.[80]

Mycophenolate is an immunosuppressant used in transplant patients to prevent rejection and in autoimmune conditions to help reduce inflammation. Maternal use of mycophenolate during pregnancy has been linked to several malformations, including craniofacial malformations with orofacial clefts. Craniofacial malformations were reported in 12 of 14 infants exposed to mycophenolate during development.[73,81-91] Seven of the infants had an orofacial cleft with four cases of cleft lip and palate, two cases of cleft palate, and one case of bilateral oblique facial cleft.

Isotretinoin was approved for use in the United States in 1982. Shortly after approval, several publications appeared warning of the human teratogenic potential associated with isotretinoin use during pregnancy or in women who may become pregnant. From September 1982 through July 1984, the FDA and Centers for Disease Control and Prevention (CDC) received reports of 154 isotretinoin-exposed pregnancies. In total, 95 were electively aborted, 12 aborted spontaneously, 21 had major malformations, and 26 infants were born without major defects. Of the 21 infants with major malformations, 3 were stillborn and 9 expired shortly after birth.[92-97] Malformations observed in the 21 infants included CNS defects, craniofacial defects, cardiovascular defects, brachial-arch mesenchymal-tissue defects, thymal defects, spina bifida, nystagmus, hepatic abnormalities, hydroureter, decreased muscle tone, large scrotal sac, and limb reduction.[98-102]

Data from the National Birth Defects Prevention Study (NBDPS) that investigated deliveries from 1997 to 2002 demonstrated an increased risk of cleft lip with or without cleft palate (OR 1.7, 95% CI 1.1–2.6) but not cleft palate only (OR 0.5, 95% CI 0.2–1.3) from maternal corticosteroid use.[103] Data collected between 2003 and 2009 showed an association between corticosteroids and cleft lip and palate (OR 1.0, 95% CI 0.7–1.4).[104]

Results of studies searching for a link between maternal benzodiazepine use and infant orofacial cleft development have been mixed. A positive association has mostly been found in retrospective case-control analyses, which raises concerns of recall bias. A meta-analysis evaluating all studies from 1966 to 1998 found no association between benzodiazepine exposure during pregnancy and cleft development (OR 1.19, 95% CI 0.34–4.15).[74] An additional review of 1,979 infants whose mothers reported taking benzodiazepines during pregnancy did not show an increased risk in orofacial clefts.[105] However, a more recent meta-analysis of over 1 million pregnancies found a twofold increased risk of oral cleft development in infants of mothers exposed to benzodiazepines during pregnancy.[106]

Bronchodilators are often needed to treat patients with asthma during pregnancy. A few studies have looked for an association between bronchodilator use during pregnancy and development of orofacial clefts. One study utilized the NBDPS to compare 2,711 infants born with orofacial clefts to 6,482 infants born without defects. Information regarding maternal medication use from 3 months before pregnancy to delivery was evaluated and reviewed. Albuterol was the most commonly used bronchodilator in this population and was used by 88.7% of the mothers who were exposed to bronchodilators. An association between bronchodilator use and cleft lip development was observed (adjusted OR 1.77, 95% CI 1.08–2.88). A trend toward an increased cleft palate development risk was also observed, but statistical significance was not achieved (adjusted OR 1.53, 95% CI 0.99–2.37). Maternal albuterol use was associated with cleft lip development (adjusted OR 1.79, 95% CI 1.07–2.99) and cleft palate development (adjusted OR 1.65, 95% CI 1.06–2.58). The authors were careful to note that it is unclear from their study if the increased risk of orofacial clefts is due to maternal exposure to bronchodilators, an increased severity of asthma, a combination of these factors, or chance.[107]

MECHANISMS

The mechanism of orofacial cleft development is not well understood, but it occurs when there is failure of the fusion of nasal processes and/or palatal shelves.[108] The exact etiology of cleft palate and lip development remains unknown; however, there are several risk factors associated with an increased prevalence. It is hypothesized that anything that disrupts cell proliferation, migration, adhesion, differentiation, or apoptosis involved in the growth and fusion on the face and palate before the end of week 6 of gestation can lead to development of a cleft lip and or cleft palate. Similar to most congenital malformations, genetics and chromosome disorders play a role in the increased risk of developing clefts. The teratogenic mechanism of isotretinoin is thought to result from an adverse effect on the initial differentiation and migration of cephalic neural crest cells.[109,110]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Orofacial clefts, specifically cleft lip with or without cleft palate, are typically diagnosed during pregnancy through routine ultrasound. Some may be diagnosed after the baby is born, and this is often the case with cleft palates. Certain types of cleft palate (e.g., submucous cleft palates and bifid uvula) may not be diagnosed until later in life due to difficulty with detection. Children with clefts often suffer from abnormal nasal speech and speech difficulties, which can lead to further evaluation and discovery of the malformation. Differential diagnosis includes facial teratoma, frontonasal dysplasia, premaxillary agenesis, and amniotic band syndrome.[111]

RISK FACTORS

Exposure to known causative agents during pregnancy increases the risk of orofacial clefts. In addition, an association has been identified between maternal well-being throughout the pregnancy and the development of fetal orofacial clefts. There is an association between maternal weight and cleft development with an increased risk of malformation in both over- and underweight patients.[112,113] Febrile infections during early pregnancy have also been associated with development of clefts in the fetus.[114] Interestingly, acetaminophen use during the first trimester of pregnancy appears to reduce the risk of cleft development and appeared to decrease the risk of development in women who reported concomitant febrile infections in early pregnancy.[115] Pregestational diabetes has also been linked to oral cleft development.[116] The key to prevention is achieving well-controlled blood glucose levels prior to and during early pregnancy.

Vitamin and mineral deficiencies, specifically vitamin B_6 and zinc deficiencies, have also been associated with an increased risk of orofacial clefts.[117,118] Smoking and alcohol exposure during pregnancy have been tied to increased risk of orofacial clefts, as have maternal amphetamine, cocaine, and ecstasy use.[119,120]

MORBIDITY AND MORTALITY

Children born with facial clefts have a significantly increased mortality risk compared to the baseline population.[121] One cohort study of 432,238 live births found a mortality rate of 36 per 1,000 cleft births.[121] More than 90% had anomalies in other organ systems in addition to the orofacial cleft, and those anomalies likely impacted the reported mortality rate. Treatments for children born with orofacial clefts will vary depending on the severity of the cleft. It is generally recommended that children have surgery to repair a cleft lip within the first 12 months of life and surgery to repair cleft palate within the first 18 months.[122] Often children will need additional surgeries as they get older and their facial structures continue to grow and develop. Depending on the cleft type, the child may face problems feeding and/or speaking clearly, may experience an increased risk for ear infections, and may have dental and hearing issues.

CONGENITAL HEART DEFECTS

Congenital heart defects represent the most common type of birth defect, and there are several different types of congenital cardiac malformations that may be present at birth. These vary in presentation and can affect both the structure and the function of the heart.

CAUSATIVE AGENTS

Maternal exposure to valproic acid, thalidomide, isotretinoin, lithium, risperidone, and selective serotonin reuptake inhibitors (SSRIs) during pregnancy has been associated with a possible increased risk for heart defects in the neonate.[123-126] A relatively low prevalence of congenital heart defects and the relatively small number of expectant mothers exposed to these drugs makes it difficult to obtain large enough samples to prove true associations.

EPIDEMIOLOGY

Congenital heart defects occur in 50–150 births per every 10,000.[127] The overall incidence of drug-induced congenital heart defects is unknown. The incidence of cardiac malformations associated with use of specific agents during pregnancy, where known, is discussed in further detail below.

Maternal valproic acid use during pregnancy has been linked to cardiac defects in the developing fetus, specifically anomalies of great vessels, patent ductus arteriosus, valvular aortic stenosis, ventricular septal defect, atrial septal defect, and Tetralogy of Fallot.[128-134] One large cohort study evaluated 1,565 expectant mothers exposed to valproic acid and compared findings to controls not exposed to any antiepileptic therapy. Investigators found an increased risk for atrial septal defects (adjusted OR 2.5, 95% CI 1.4–4.4); however, there was no increased risk for other cardiac defects.[135]

Thalidomide exposure during pregnancy has frequently been linked to cardiovascular abnormalities, including ventricular septal defects, atrial septal defects, Tetralogy of Fallot, cor triloculare, pericardial effusion, hypertrophy of atrium and ventricle, coarctation of the aorta, and systolic murmurs.[125,136-139] Cardiac defects occurring after thalidomide exposure have also been identified as a major cause of early death. Thalidomide-associated early death occurs in 30% of infants at birth and occurs in up to 6% of the survivors.[140] Overall, exposure to thalidomide during pregnancy has been associated with an estimated 20–50% increased risk of congenital malformation development.[140]

Exposure to isotretinoin during pregnancy has been linked to several cardiovascular malformations, including transposition of the great vessels, Tetralogy of Fallot, double-outlet right ventricle, truncus arteriosus communis, ventricular septal defects, and atrial septal defects.[126] It is difficult to determine the true incidence of isotretinoin-induced malformation because many pregnancies that occur in exposed patients are aborted either electively or spontaneously.

In a cohort study of 1,360,101 pregnant women, risperidone was associated with a small increased risk in cardiac malformations (RR 1.26, 95% CI 0.88–1.81) when risk was evaluated independently of potential confounders. Specifics of the malformation were not specified, however.[123] The authors expressed concern for potential selection bias, as the cohort only analyzed live births, potentially missing any malformation documented in early pregnancy that resulted in spontaneous abortions, stillbirths, or planned terminations.

Some literature suggests an association between lithium and an increased risk of Ebstein anomaly, which results in a downward displacement of the tricuspid valve within the right ventricle. In one study of 225 case reports of infants exposed to lithium during pregnancy, a total of 18 infants were found to have a cardiovascular birth defect. Six of these were Ebstein anomaly (1:20,000 births or 0.5% of all cardiac heart defects).[141] Another cohort study evaluated 59 infants exposed to lithium throughout pregnancy and found that 4 were born with a congenital heart defect but none had Ebstein anomaly.[142] Two additional studies evaluated 233 infants born with Ebstein anomaly and found that none of the mothers had been exposed to lithium during their pregnancies.[143,144] The Motherisk Program conducted a prospective, controlled study of 148 women treated with lithium during the first trimester of pregnancy and found that the incidence of infants born with major malformations to women exposed to lithium was no higher than those in the control group.[145] Although early data suggested an association between lithium exposure and Ebstein anomaly, more recent work suggests the risk for Ebstein anomaly with lithium is much lower than originally estimated.

Prior to 2005, SSRIs were considered relatively safe for use during pregnancy. In general, their use had not been found to carry an increased risk of major malformations over the baseline of 1–3% found in the general population. Since then, several studies found SSRIs associated with an increased risk for cardiovascular malformations—in particular, ventricular septal defects.[146,147] The first studies suggested paroxetine might be associated with an increased risk for septal defects.[146,147] A population-based prevalence study was done and evaluated 2,062 women with SSRI prescriptions during early pregnancy compared to 213,712 women with no SSRI prescriptions. A total of 362 infants were diagnosed with a cardiac malformation and 9 of these were infants whose mothers took SSRIs during pregnancy. SSRI use was associated with an increased risk of cardiac malformations (OR 1.7, 95% CI 1.1–2.5). Sertraline was associated with a threefold increased risk (OR 3, 95% CI 1.4–6.4). SSRI use was associated with an increased risk of septal defects (OR 1.4, 95% CI 0.8–2.3), as was sertraline (OR 3.3, 95% CI 1.5–7.5) after adjusting for maternal smoking status, maternal age, birth order, and birth age.[148] Two additional studies also found an elevated risk of septal defects associated with sertraline use.[149,150]

Some studies have reported a slight risk of cardiac malformation when paroxetine or fluoxetine has been used during the first trimester of pregnancy, but a number of other studies report no increased risk.[124] One study observed a relationship between the dose of paroxetine used during pregnancy and the risk of cardiac malformation, although that finding was not replicated in a subsequent study.[151,152] A meta-analysis conducted in 2010 reported an increased prevalence of cardiac malformations (OR 1.46, 95% CI 1.17–1.82) after paroxetine use in the first trimester of pregnancy.[153] NBDPS completed an analysis that found paroxetine and fluoxetine use during pregnancy was associated with a high risk of several subtypes of congenital heart anomalies. Paroxetine was associated with atrial septal defects (OR 1.9, 95% CI 1.1–3.0) and right ventricular outflow tract obstruction defects (RVOTO) (OR 2.4, 95% CI 1.4–3.9). Fluoxetine was associated with RVOTO (OR 2.0, 95% CI 1.4–3.1) and ventricular septal defects (OR 1.4, 95% CI 1.0–1.9).[154] Studies have not found the same risks for cardiac malformation with sertraline exposure.[154]

Interestingly, studies have found infants born to women exposed to SSRIs undergo approximately twice as many echocardiograms in the first year of life when compared to infants not exposed to SSRI therapy. This likely leads to an increased chance for diagnosis of a cardiac malformation.[155] An estimated 85–90% of ventricular septal defects close spontaneously during infancy.[156] The likelihood of finding a ventricular septal defect, whether the child was exposed to SSRIs during development or not, would be expected to decrease when the assessment is done later in childhood. This creates an additional opportunity for bias in research results.

MECHANISMS

The exact cause of most cardiac malformations is unknown, but most are due to sporadic genetic causes such as focal mutations and DNA segment deletions or additions.[157] Down syndrome has been linked to congenital heart disease in roughly 45% of cases, although researchers have not been able to isolate a single gene on chromosome 21 that is responsible for heart defects.[158] Family history also seems to play a large role and can often help identify heritable defects.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Infants with congenital heart defects will present differently depending on the defect's type and severity. Some signs and symptoms may include tachypnea, cyanosis, fatigue, and poor blood circulation; however, many heart defects cause few or no signs or symptoms.[159] Babies who have congenital heart defects may have cyanosis and tire easily during feeding times, which may lead to slower weight gain. Older children with congenital heart defects may tire more easily or get short of breath during physical activity when compared to other children.

Severe congenital heart defects are generally detectable and diagnosed during pregnancy via fetal echocardiography around weeks 18–22 gestation, or very soon after birth. Depending on the defect's severity, cardiac catheterization or surgery may be required to repair damage. When the defect is less severe, it is often not diagnosed until the child is older. Minor defects that have no signs or symptoms are often diagnosed based on results from a physical exam or tests completed for other complaints.

RISK FACTORS

Several maternal factors have been linked to the development of fetal congenital heart defects, including pre-existing uncontrolled diabetes, obesity, rubella, and influenza.[160] Additionally, maternal smoking and the use of cocaine and marijuana have also been linked to cardiovascular defects. Children who acquire HIV infections from their mothers during pregnancy are at increased risk for cardiovascular defects, but children born to mothers infected with HIV and treated are not at increased risk.[160]

MORBIDITY AND MORTALITY

The incidence of morbidity or mortality associated with drug-induced congenital cardiac malformations is unknown. In general, depending on the degree of malformation, surgical repair may be necessary within the first few days after delivery. Additional surgeries may be required throughout development as the heart continues to grow. In severe cases, heart transplant may be necessary. Not all infants with congenital heart defects will require treatment. Some may only require observation and periodic reevaluation of cardiac function.

LIMB DEFICIENCY DEFECTS

Limb deficiency defects vary greatly and can be characterized by total or partial absence of a limb or smaller defects such as a missing finger or toe. They can occur as a single malformation or in conjunction with other anomalies. Limb development is complex and starts as a small limb bud on the 26th day after fertilization with the upper limb developing about 24 hours before the lower.[161]

CAUSATIVE AGENTS

Prenatal exposure to several medications has been linked to an increased risk of limb malformation. Although thalidomide is perhaps best known for this teratogenic effect, misoprostol, valproic acid, aminopterin, methotrexate, phenytoin, and isotretinoin have all been associated with limb reduction.[162-166]

EPIDEMIOLOGY

Limb deficiency defects are rare, occurring in only 3–8 infants per 10,000 live births, and it is estimated at least 30% are associated with congenital malformations.[167-172] The most common type of limb defect is caused by vascular disruption and occurs in an estimated 2.2 infants per 10,000 births.[169] The overall incidence of drug-induced limb deficiencies is unknown.

Thalidomide exposure during pregnancy has been linked to limb reduction defects which are described as bilateral and usually grossly symmetrical. Exposure has been associated with approximately 20% incidence of polydactyly, syndactyly, and limb reduction defects.[173]

Maternal use of misoprostol has been correlated with terminal vascular disruption limb anomalies in the developing fetus.[174] The most common limb defects following misoprostol exposure include terminal transverse defects in the arms and legs, including terminal limb amputation with constriction rings, fusion of fingers with constriction rings, clubfoot, and arthrogryposis.[175-177]

In 2000, a study estimated the risk of valproic acid-induced limb deficiencies that utilized data from the Spanish Collaborative Study of Congenital Malformations. A total of 22,294 malformed infants were compared to 21,937 control infants. A total of 57 infants with malformations had been exposed to valproic acid compared to 10 infant controls with no history of valproic acid exposure (OR 5.62, 95% CI 2.78–11.71, p <0.0000001). Congenital limb defects occurred in 21 of the 57 infants exposed to valproic acid (36.8%) and included overlapping digits, clubfoot, clinodactyly, arachnodactyly, hip dislocation, pre- and postaxial polydactyly, and limb deficiencies. Based on the prevalence of limb deficiencies of 6.88 per 10,000 live births in their population, the authors estimated the risk of limb deficiencies after valproic acid exposure during the first trimester to be about 0.42%.[178]

Aminopterin, an antineoplastic drug with immunosuppressive properties often used in chemotherapy regimens, was used unsuccessfully in the 1950s and 1960s as an abortifacient agent. It has been associated with clubfoot, short forearm development, and syndactyly, although the incidence is difficult to estimate because the data are limited.[179,180]

Maternal methotrexate exposure has been associated with an increased risk for total transverse limb deficiencies, with clubfoot, short limbs, hypodactyly, and syndactyly being most commonly reported.[181-183] A disproportionality analysis found total transverse limb deficiencies in 22 cases, 6.41%, compared to only 0.85% in the general population, supporting a possible association with methotrexate exposure and limb deficiencies.[184]

Phenytoin exposure during pregnancy has well-documented teratogenic effects on skeletal tissues leading to limb defects, including hypoplasia of distal phalanges, shortness of metacarpals, cone-shaped epiphyses, limited movements at interphalangeal joints, and tapering fingers with nail hypoplasia.[185-187] It is estimated that one-third of children exposed to phenytoin in utero will suffer from fetal growth restrictions leading to small head, will develop minor dysmorphic craniofacial features, and/or will have limb defects.[174]

Isotretinoin has also been linked to limb deficiency defects, specifically limb reduction. A case report in 1985 first reported limb reduction deformities secondary to isotretinoin exposure in a male infant born with reductions in all four limbs. There was some evidence suggesting the defects were secondary to amniotic bands.[188,189] There have been additional subsequent reports describing cases of infants born with limb reductions following exposure to isotretinoin in utero.[190]

MECHANISMS

The exact cause of limb defects is unknown, although it is thought to be due to disruptive events, including amniotic bands or vascular disruptions that can lead to in utero amputation or hypoperfusion of the developing limb.[191] Cases of limb defects caused by exposure to misoprostol during pregnancy are thought to be related to the induction of uterine contractions that deform the embryo. This results in vascular disruption, hemorrhage in various tissues that leads to hypoperfusion within the entire embryo, resulting in cellular death.[174,192]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Limb deficiency defects can present in a variety of ways, including complete absence of the limb, failure of a portion of the limb to separate (most commonly seen in fingers or toes), duplication (most commonly seen in fingers or toes), overgrowth where the limb is much larger than normal, undergrowth where the limb is much smaller than normal, or congenital constriction band syndrome, which causes immobilization, constrictions of the limbs, amputations, and other deformities. Most limb deficiencies are diagnosed on visual inspection at birth and are immediately recognized and identified.

RISK FACTORS

The majority of limb defects are caused by genetic or chromosomal disorders; however, there are other known associated risks as well. Pregestational maternal diabetes and maternal obesity have been identified as possible risk factors for disorders of limb development, although the data regarding the effects of obesity are inconsistent.[112,193-197] Additionally, certain sets of limb deformities have been linked to other birth defects such as those involving the heart, omphalocele, and gastroschisis.[198]

MORBIDITY AND MORTALITY

The incidence of morbidity or death associated with drug-induced limb deficiencies is unknown. Infants born with limb reduction defects will face many obstacles and difficulties throughout development, and the extent of impact will depend on the limb(s) affected and the size of the reduction. Problems include difficulties performing motor skills, need for assistance with daily activities and self-care, limitations in movement, and potential for emotional and social issues due to physical appearance. The use of prosthetics and orthotics may be beneficial for patients with limitations due to limb reduction. In some cases, surgery and rehabilitation with physical and or occupational therapy may be needed. Although children born with limb reductions may face many obstacles and encounter difficulties throughout life, with proper treatment and care they are able to live healthy and productive lives and most manage well in everyday life.[199]

GASTROSCHISIS

Gastroschisis is a defect that occurs in developing fetuses that results in extrusion of the intestines out of the abdominal wall and into the amniotic space. Typically, the intestines protrude to the right of the umbilicus and the anomaly can be detected in utero via ultrasound. The size of hole can vary, and sometimes organs, such as the stomach and liver, can also protrude outside of the baby's body (**Figure 58-3**).

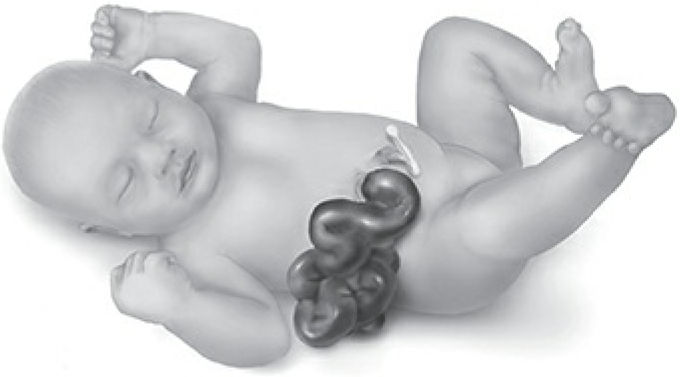

FIGURE 58-3 Gastroschisis

Source: Centers for Disease Control and Prevention, National Center on Birth Defects and Developmental Disabilities. http://www.cdc.gov/ncbddd/birthdefects/gastroschisis.html.

CAUSATIVE AGENTS

Prenatal exposure to several medications has been associated with an increased risk of gastroschisis. Evidence, although weak, suggests that women taking anti-inflammatory doses of aspirin or taking acetaminophen in combination with other medications may be at increased risk.[200] Literature has also linked prenatal pseudoephedrine use to gastroschisis, although, again, evidence is weak and reports are inconsistent.[201,202]

EPIDEMIOLOGY

In the United States, gastroschisis occurs in 1–2 of every 10,000 births, and the incidence has increased over the last three decades.[203] The overall incidence of drug-induced gastroschisis is unknown and difficult to estimate based on available literature.

A retrospective study evaluating 206 cases of gastroschisis looked at the relationship between maternal use of cough, cold, and analgesic medications and development of gastroschisis. Risk of gastroschisis development was elevated in patients exposed to aspirin (OR 2.7, 95% CI 1.2–5.9). Risk was slightly elevated in infants whose mothers took acetaminophen during pregnancy (OR 1.5, 95% CI 1.1–2.2) but was significantly elevated in those exposed to acetaminophen in combination with pseudoephedrine (OR 4.2, 95% CI 1.9–9.2).[200]

Three case-control studies examined pseudoephedrine monotherapy exposure in children born with gastroschisis. In all three studies, exposure to pseudoephedrine was associated with an increased odds ratio. In one study, the risk of gastroschisis was increased 4.2-fold in women taking pseudoephedrine in combination with paracetamol (95% CI 1.9–9.2).[204] However, two other studies reported data from over 400 pregnant women who took pseudoephedrine during the first trimester, and neither study found an increase in the incidence of birth defects.[205,206]

MECHANISMS

The exact cause of gastroschisis is unknown, although it is thought to be due to a vascular disruption causing a weakness in the body wall, possibly to the right umbilical vein or the right vitelline artery.[207,208] Other proposed mechanisms include defective growth, cellular death, or impaired cellular fusion that leads to extrusion of the intestines through the defective area and into the amniotic fluid.[209] Furthermore, genetic or chromosomal changes that occur in utero cannot be ruled out as a potential cause.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Gastroschisis is typically diagnosed during routine anatomy ultrasound conducted around 20 weeks gestation.[210] The ultrasonography can be performed to detect signs of intestinal injury, decreased peristalsis, and/or bowel distension. In rare scenarios, gastroschisis may not be diagnosed until after delivery. An omphalocele, another abdominal wall defect, is an umbilical cord hernia with a wall defect <4 cm. Maternal elevations of serum alpha-fetoprotein are associated with abdominal wall defects, and levels are generally higher in cases of gastroschisis compared to omphalocele. This difference can aid in initial diagnosis.[211] The differential diagnosis of gastroschisis includes normal physiological gut herniation, ruptured omphalocele, umbilical cord cysts, or loops of normal umbilical cord.[212]

RISK FACTORS

The most consistently observed link to gastroschisis is a mother’s age of <20 years, although the reason for this is unclear.[213-215] The impact of maternal prepregnancy body mass index on the development of gastroschisis has been evaluated. One study noted an increased risk in underweight mothers when compared to normal weight mothers.[216] In addition, two other studies found a lower risk in mothers who were overweight or obese when compared to normal weight women, advancing the theory that maternal prepregnancy weight has an impact on fetal development.[112,113] Maternal cigarette smoking has also been linked to an increased risk of both gastroschisis and small-bowel atresia, with risk increasing with the number of cigarettes smoked. A study of 205 gastroschisis cases and 127 small-bowel atresia cases found maternal cigarette smoking to have an increased odds ratio of 2.1 (95% CI 1.0–4.4) for gastroschisis and 2.8 (95% CI 1.1–6.9) for small-bowel atresia.[217]

Other risk factors for gastroschisis include maternal alcohol consumption and exposure to illicit drugs, specifically marijuana, cocaine, and methamphetamine.[214,217-220]

MORBIDITY AND MORTALITY

The incidence of morbidity or mortality associated with drug-induced gastroschisis is unknown. In general, the survival rate for those with gastroschisis is remarkably high, exceeding 90% after surgical closure; however, babies tend to suffer varying degrees of morbidity depending on the severity of bowel injury.[221] Infants with gastroschisis may struggle with feeding, digesting food, and absorbing nutrients after eating. The extent of dysfunction usually depends on the magnitude of intestinal inflammation and ischemic injury caused by amniotic fluid exposure and compression from the abdominal wall. The inflamed intestine often has prolonged transit time and decreased absorption of carbohydrates, fats, and proteins. As the inflammation subsides, transit time and absorption return to normal over 4–6 weeks, although total parenteral nutrition is often required during healing. Some may require additional surgeries throughout childhood and in severe cases, may endure intestinal failure.

NEURAL TUBE DEFECTS

Neural tube defects are a collection of anomalies of the CNS that develop within the first 28 days after conception. They occur due to incomplete closure of the neural tube during embryogenesis, causing exposure to neural elements.[222] The most common neural tube defects are spina bifida, meningomyelocele, anencephaly, and encephalocele.

Spina bifida can occur at any point along the spine. The spinal area around the opening does not form properly, leaving the spinal cord exposed (**Figure 58-4**). Often, this leads to damage to the spinal column and surrounding nerves. The severity is determined by the size and location of the opening in the spine and whether nerve damage is involved.

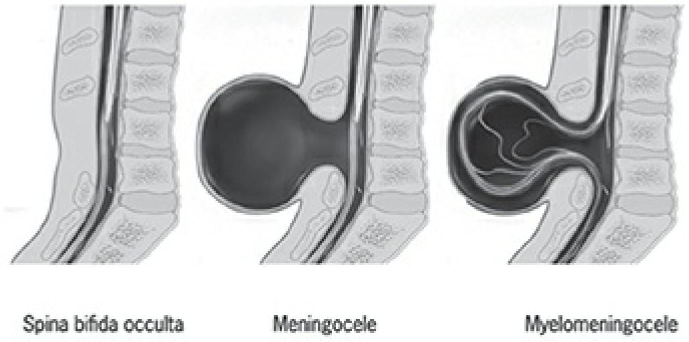

FIGURE 58-4 Spina Bifida

Source: Centers for Disease Control and Prevention, National Center on Birth Defects and Developmental Disabilities. http://www.cdc.gov/ncbddd/spinabifida/facts.html.

With anencephaly the upper portion of the neural tube does not close completely and the forebrain and cerebrum do not form. Additionally, the remaining portions of the brain are often not covered by bone or skin and are exposed at birth (**Figure 58-5**).

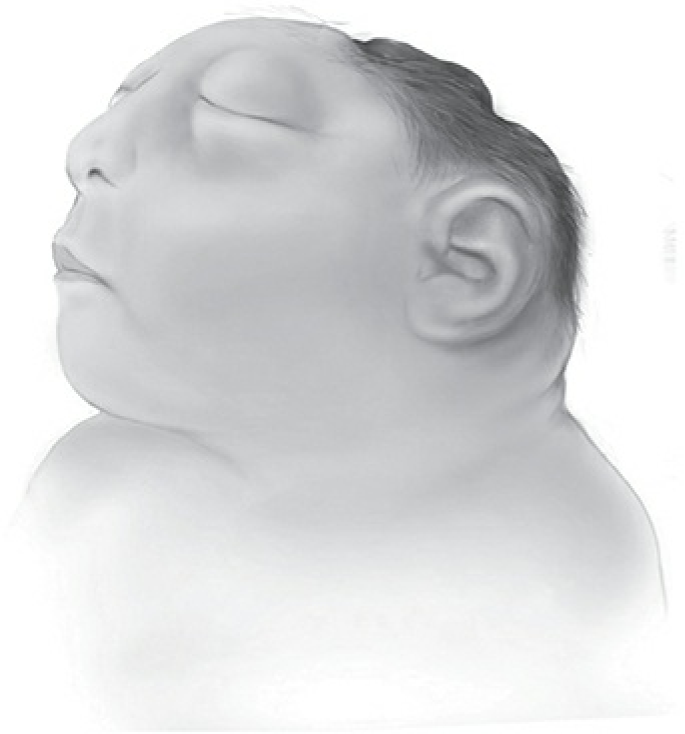

FIGURE 58-5 Anencephaly

Source: Centers for Disease Control and Prevention, National Center on Birth Defects and Developmental Disabilities. http://www.cdc.gov/ncbddd/birthdefects/anencephaly.html.

Encephalocele is a rare neural tube defect associated with a sac-like protrusion at either the upper part of the skull, the area between the forehead and nose, or the back of the skull. The brain protrudes through these openings in the skull (**Figure**

58-6). The condition is typically diagnosed at birth, but occasionally a small encephalocele can protrude into the nose and forehead region and can go undetected.

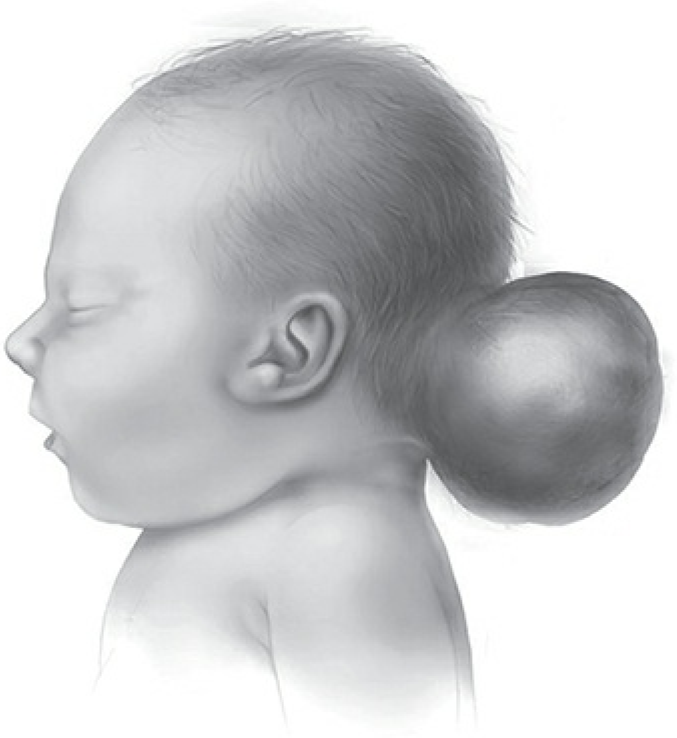

FIGURE 58-6 Encephalocele

Source: Centers for Disease Control and Prevention, National Center on Birth Defects and Developmental Disabilities. http://www.cdc.gov/ncbddd/birthdefects/encephalocele.html.

CAUSATIVE AGENTS

Several antiepileptic medications, in particular valproic acid and carbamazepine, interfere with the body's ability to utilize folate and folic acid and are associated with a higher risk for neural tube defects.[222]

EPIDEMIOLOGY

Annually, more than 300,000 babies are born worldwide with neural tube defects, making this one of the most commonly encountered birth defects. The highest incidence reported is in Northern China (3.7 cases per 1,000 live births).[223] In the United States, the incidence is much lower with a frequency of about 2 per 1,000 live births. The most recent U.S. data estimate the incidence of spina bifida at 1 case per 2,858 live births annually, anencephaly at 1 case per 4,859 live births annually, and encephalocele at 1 case per 12,235 live births annually.[224] The frequency of neural tube defects is decreasing due to the prophylactic prenatal administration of folate, implementation of universal maternal serum alpha-fetoprotein screening, and highly reliable ultrasound diagnosis.[225] The estimated risk of neural tube defects in infants with prenatal exposure to valproic acid is 5–9%, with higher doses associated with higher risks.[226,227]

MECHANISMS

The exact cause of neural tube defects is not known with many factors likely playing a role, including chromosomal disorders, genetic syndromes, nutrition, and/or exposure to environmental teratogens. Phenytoin and carbamazepine induce cytochrome P450 enzymes and are associated with a reduction in serum and red blood cell folate concentrations of up to 90%.[228] Although data are conflicting, it is thought that valproic acid may interfere with folate metabolism by inhibiting glutamate formyl transferase, an enzyme mediating the production of folinic acid.[229] Research has found that folic acid supplementation before and during pregnancy can greatly reduce the risk of neural tube defect development.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Neural tube defects are generally diagnosed prior to birth through laboratory tests or imaging. Prenatal ultrasound is routinely used during pregnancy and can detect almost all types of neural tube defects.[230] Ultrasound will typically reveal a defect in the dorsal aspect of the spine which usually has an overlying cystic mass. The differential diagnosis includes sacrococcygeal teratoma, lumbosacral lipoma, sirenomelia, limb-body stalk anomaly, and amniotic band syndrome.[231]

Infants born with a known or suspected neural tube defect will undergo a variety of tests and procedures to help understand the severity of the defect and to assess for the presence of complications. Evaluation typically will include x-rays, magnetic resonance imaging, computed tomography scans, and measurement of head circumference. In addition, the infant’s vigor, motor and sensory functioning, and urinary stream will be monitored and evaluated.[232]

Babies born with spina bifida often develop hydrocephalus (i.e., extra fluid in and around the brain). This can lead to swelling in the ventricles of the brain and cause the head to swell. It can be diagnosed during a routine prenatal ultrasound, but it is often not discovered until infancy or early childhood. The most common symptoms of hydrocephalus is a large head that is growing rapidly, a bulging anterior fontanelle, irritability, seizures, and delays in development. Close monitoring is required in an effort to prevent brain injury, and often a shunt is needed to allow drainage of the fluid and relieve pressure on the brain.

RISK FACTORS

Maternal uncontrolled pregestational diabetes and obesity have been linked to increased risk for development of neural tube defects.[233] Some studies have also suggested that defects are more common among infants of mothers who were exposed to high temperatures that may occur during a febrile illness or using a hot tub or sauna during the first 4–6 weeks of pregnancy.[234] Women who are pregnant or may become pregnant should avoid using hot tubs or saunas. Folate deficiency is the most clearly established risk factor for development of a neural tube defect. Folic acid supplementation is critical for the prevention of neural tube defects and should be an important part of preconception and prenatal care for all women of childbearing age. Due to increased risk associated with folate deficiency, the CDC recommends 0.4 mg/day of folic acid from diet or supplements for all women capable of becoming pregnant to reduce the risk for neural tube defects. Women with a history of pregnancy with a neural tube defect should take 4 mg of folic acid beginning 1 month prior to conception and throughout the first trimester of pregnancy.[235]

MORBIDITY AND MORTALITY

The morbidity and mortality arising from neural tube defects depends on the type of defect present. Anencephaly is incompatible with life.[236] The life of infants born with anencephaly is usually limited to a few hours and rarely can last more than 2 days. The brain stem in these patients consists of poorly differentiated neural tissue that is not able to sustain life.

The prognosis for neonates diagnosed with encephalocele is dependent on whether there is herniation of brain tissue into the meningeal sac. If brain tissue herniation is present, there is a high mortality rate.[237]

The prognosis of neonates with spina bifida depends on the size and location of the lesion. Generally, the lower the location of the lesion on the back and the smaller the size, the better the infant's outcome will be. Mortality is reported to be at least 15% in the first year of life, usually due to decline in respiratory function secondary to hindbrain herniation.[237] Additionally, patients often have lower limb paresis, bladder denervation, renal failure, and progressive obstructive hydrocephaly.

MICROCEPHALY

Microcephaly is a CNS defect wherein the baby's head is much smaller than would normally be expected. It is defined as a head circumference 2–3 standard deviations below the mean for the gestational age on standardized charts.[238] This is typically due to a failure of the baby’s head to grow properly or growth stopping after birth (**Figure 58-7**).

Baby with
Severe Microcephaly

FIGURE 58-7 Microcephaly

Source: Centers for Disease Control and Prevention, National Center on Birth Defects and Developmental Disabilities. http://www.cdc.gov/ncbddd/birthdefects/microcephaly.html.

CAUSATIVE AGENTS

Use of antiepileptic drugs, including carbamazepine, lamotrigine, phenytoin, valproic acid, and topiramate, as well as mycophenolate and methotrexate, has been associated with an increased risk of microcephaly.[184,239-241]

EPIDEMIOLOGY

Microcephaly is estimated to occur in 2–12 babies of every 10,000 live births in the United States. It can be an isolated malformation or occur in conjunction with other major and minor birth defects.[242]

Although the exact incidence of drug-induced microcephaly is unknown, some data regarding specific drug exposure and incidence are available. One study evaluated 329 pregnant women with epilepsy who were treated with monotherapy using carbamazepine, lamotrigine, phenytoin, or valproic acid. Authors observed microcephaly rates of 12–13% in newborns of mothers exposed to any of the anticonvulsants: however, the rates decreased to 3% when the children reached 24 months of age and 2% at 36 months of age.[239] Carbamazepine had the highest incidence of microcephaly (24%) in neonates and 12-month-old infants (15 out of 63 exposed) and valproic acid was the next highest at 18% (7 out of 40 exposed). However, total rates of microcephaly at 24 months and 36 months for children exposed to all study drugs were similar to population rates for microcephaly. Similar results of higher microcephaly rates with carbamazepine and valproic acid monotherapy have been reported in previous studies, although these studies did not follow patients past 18 months of age to determine if the impact was long-term or resolved.[243,244] The clinical implications of early microcephaly are unclear, and it appears the effect is not permanent or regulates with time. An additional study evaluating the impact of antiepileptic drug exposure on newborn head circumference reported a significant reduction of mean body-weight adjusted head circumference after exposure to carbamazepine and valproic acid monotherapy (standard deviation 0.15, p <0.0001, and standard deviation 0.10, p = 0.04, respectively). No effect on body-weight adjusted head circumference was seen for phenytoin, clonazepam, lamotrigine, or gabapentin. Additionally, the study reported a significant increase in the occurrence of microcephaly for any antiepileptic drug polytherapy (OR 2.85, 95% CI 1.74–4.78), suggesting risk is greatest in patients exposed to multiple antiepileptic drugs during pregnancy.[243]

A cohort study compared 2,600 children exposed to antiepileptic drugs during pregnancy to 771,412 unexposed children born to women without epilepsy. The study found infants exposed to topiramate had a considerable risk of microcephaly

(11.4%) compared to 2.4% in those who weren't exposed (OR 4.8, 95% CI 2.5–9.3).[240]

Mycophenolate was linked to risk for microcephaly in one case. Microcephaly was mild, and the child had various other malformations.[241]

Maternal methotrexate exposure during pregnancy has also been linked to microcephaly. Three published cases describe infants with microcephaly (in addition to various other malformations) following maternal exposure to methotrexate for either abortion or during treatment for breast cancer.[245,246] Hyoun et al.[184] completed a disproportionality analysis and found microcephaly occurred with an incidence of 0.87% after methotrexate exposure—an incidence not disproportionate to that found in the general population.

MECHANISMS

The cause of microcephaly is not fully understood; however, it is known that this defect is multifactorial and is the common end point of a group of heterogeneous conditions that interfere with the growth of the brain. It occurs as a result of abnormal cell division and proliferation.[247]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The key diagnostic feature of microcephaly is an infant with a head circumference >3 standard deviations below the mean. The head may appear smaller than normal on visual inspection and biometric parameters other than head circumference may also be small (e.g., biparietal diameter, cerebellar diameter). A reduced frontal lobe distance, sloping forehead, or a large subarachnoid space may also be present.[248] The differential diagnosis includes anencephaly, hydrocephaly, and brain atrophy.[249]

RISK FACTORS

Although the direct cause of microcephaly is unknown, certain maternal infections such as rubella, toxoplasmosis, cytomegalovirus, and Zika virus are associated with the development of fetal microcephaly.[250] The defect is also linked to genetic changes, although the genetic sequencing is currently unknown. Neonates whose mothers were malnourished during pregnancy are at increased risk. Maternal alcohol consumption and exposure to cocaine during pregnancy have also been linked to an increased risk of microcephaly.[251,252]

MORBIDITY AND MORTALITY

The overall impact of microcephaly varies depending on the severity. Some children only suffer from mild disabilities while others, especially those who are growing and developing normally, will have normal intelligence levels and continue to meet major milestones. There is no treatment that will return the size of the child's head to normal size or shape. Treatment is focused on preventing and minimizing complications and may include speech, physical, and occupational therapy as well as medications to control seizures and hyperactivity if and when present.

FETAL ALCOHOL SPECTRUM DISORDERS

Fetal alcohol spectrum disorders (FASD) is a group of conditions caused by alcohol consumption during pregnancy. Those conditions include fetal alcohol syndrome (FAS), alcohol-related neurodevelopmental disorder, and alcohol-related birth defects. The effects of alcohol exposure can include both physical and mental defects and can cause problems with development, behavior, and learning. Often, children with FASD have a mix of problems rather than one single issue. The conditions can affect each person differently and can vary in severity. The most severe of the alcohol-related disabilities is FAS, and individuals diagnosed are found to have growth problems (e.g., low pre- and postbirth weight and size), facial dysmorphia (e.g., small head, small eyes, underdevelopment of the upper lip, indistinct groove between the lip and nose, and/or flattened cheekbones), and CNS abnormalities (e.g., delayed brain development, intellectual impairment).[253]

CAUSATIVE AGENTS

Prenatal exposure to alcohol is associated with development of FASD.

EPIDEMIOLOGY

An accurate estimate of the prevalence of FASDs is lacking; however, the CDC has completed studies that have documented 0.2–1.5 infants with FAS for every 1,000 live births in certain areas of the United States.[254] Authors who combined community studies and expert estimates have stated the incidence might be as high as 2–5 for every 100 schoolchildren.[255,256] One report found that alcohol was used by 1 of every 10 pregnant women and 1 in 33 pregnant women described binge drinking within the last 30 days. Among those women who reported drinking during pregnancy, the highest use was in unmarried college graduates 35–44 years of age.[257]

MECHANISMS

The exact mechanism of harm secondary to alcohol exposure during pregnancy is not fully understood. Alcohol easily passes across the placenta to the developing fetus, and alcohol metabolism is much slower in the fetus compared to adults. As a result, the alcohol remains in the baby's blood much longer than in the mother's blood, which leads to possible irreversible harm to the baby's development. One recent study evaluated the effects of prenatal alcohol exposure on cognitive development in childhood and found that children with prenatal alcohol exposure have poorer axon packing density and/or myelination. The authors suggested this impairment in white matter is the likely cause of changes in information processing speed and eyeblink conditioning that commonly occur in children with FAS.[258]

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Diagnosis of FASD can be difficult because it mostly relies on infant or child clinical presentation and maternal reporting of alcohol use. Additionally, other disorders (e.g., attention deficit hyperactivity disorder) present with symptoms similar to those of FASD, which likely has led to underdiagnosis. Practitioners most often look for abnormal facial features, lower than average height, weight, or both, CNS problems, and history of prenatal alcohol exposure to help rule in or rule out FASD (**Table 58-1**).

Table 58-1 Potential Symptoms of Fetal Alcohol Spectrum Disorders[269]

- Abnormal facial features (e.g., smooth ridge between the nose and upper lip)
- Difficulty in school, especially with mathematics
- Attention deficit or hyperactivity disorders
- Poor memory
- Poor reasoning and judgment skills
- Intellectual disability or low IQ
- Learning disabilities
- Speech and language delays
- Vision or hearing problems
- Low body weight
- Shorter-than-average height
- Microcephaly
- Issues with coordination
- Problems with the heart, kidney, or bones
- Sleep and sucking problems as a baby

IQ = intelligence quotient.

RISK FACTORS

It is important to note that no amount of alcohol has been determined to be safe during pregnancy, and data support the "Not a Single Drop" approach for pregnant women. It is uncertain whether moderate drinking throughout pregnancy imparts more or less risk than binge drinking. Some data suggest that the dose of alcohol consumed does matter and has an impact on development of FASD; however, more information is needed to confirm that finding.[259] The timing of alcohol exposure during pregnancy is important. Although consumption at any time during pregnancy is not safe, alcohol is the most harmful when consumed during the first 3 months of pregnancy.[260]

MORBIDITY AND MORTALITY

The incidence of morbidity or mortality associated with FASD and FAS is unknown. Without early diagnosis, individuals with prenatal alcohol exposure are at a high risk for a number of secondary disabilities, including mental illness, homelessness, substance abuse, and unemployment. An estimated 60% of people with FASD end up being charged, arrested, convicted, or otherwise in trouble with the law, and up to 50% end up in detention, jail, prison, or a psychiatric or drug and alcohol inpatient setting at some point in their lives.[261] Additionally, it is well documented that patients with FASD or FAS-related conditions, such as mental disorders, attention deficit hyperactivity disorder, and learning disabilities, have higher mortality rates and shorter life expectancy.[262-265]

One study found the life expectancy for people with FAS was 34 years (95% CI 31–37 years).[266] The leading causes of death included suicide (15%), accidents (14%), poisoning by illegal drugs or alcohol (7%), diseases of the nervous system and respiratory system (8% each), diseases of the digestive system (7%), congenital malformations (7%), mental and behavioral disorders (4%), and disease of the circulatory system (4%).[266]

Treatment of FASD and FAS is typically focused on symptom management and may include medications, behavior and education therapy, and parental education/support.

MISCELLANEOUS MALFORMATIONS

This chapter highlights many of the major congenital anomalies; however, there are many other malformations that are associated with teratogens and can occur during fetal development. **Table 58-2** lists additional teratogens.

PREVENTION OF TERATOGENICITY

Primary prevention is a key component of avoiding congenital anomalies associated with teratogens. Teratogencity could be avoided in women who are able to completely refrain from taking medications during pregnancy, particularly during the first trimester of pregnancy. However, this is not always possible. Women with chronic diseases (e.g., diabetes, hypertension) often require pharmacotherapy prior to and throughout pregnancy to maintain their health.

Avoiding alcohol, illicit drugs, and tobacco, maintaining adequate nutrition (which should include taking a daily multivitamin that contains at least 0.4 mg of folic acid), and maintaining a healthy body weight are all essential to the primary prevention of birth defects.

It is important for women with chronic diseases to work with their healthcare providers to control their conditions prior to conception. This is particularly important for patients with diabetes, hypertension, and thyroid disorders. Medications with known risks for development of congenital anomalies should typically be discontinued prior to conception. When this is not possible (e.g., patients receiving anticonvulsant therapy for epilepsy), a careful risk versus benefit analysis should be done to determine the best approach for each individual patient. Ultimately, each patient's care plan must be individualized to determine what is best for both maternal and fetal well-being.

Secondary prevention measures are utilized to assist with early detection, treatment, and management of an existing disorder. Goals are focused on reducing, and in some cases, preventing morbidity. Early prenatal care including ultrasound screening and fetal surveillance during the first and/or second trimester is important when there is a concern for a congenital anomaly. Transferring care of the mother to a maternal fetal care center or high-risk obstetrics clinic designed for optimal fetal and neonatal care can be invaluable and should be considered where available. Delivery plans and postbirth plans including treatment and management for the infant should be discussed.

Table 58-2 Drugs with Known Teratogenic Effects[a]

Drug	Teratogenic Effects
ACE inhibitors	Fetal growth restriction, fetal hypotension, fetal renal defects leading to anuria, anuria-associated oligohydramnios, renal tubular dysplasia, craniofacial deformation, microcephaly, encephalocele, pericardial effusion, IUGR, prematurity, small bladder, and echogenic bowel associated with exposure in 2nd and 3rd trimester[270-274]
Cocaine	Miscarriage, prematurity, fetal growth restriction; developmental issues of the urinary and genital tract, heart, limbs, and face; severe neurobehavioral and neurophysiologic problems that may persist for months; placental abruption;

	and potential increased risk for sudden infant death syndrome during the first few months after birth[275-287]
Finasteride	Prostate and external genital developmental disruption in animal studies[288]
Flutamide	Inhibition of Wolffian duct and prostate development; feminization of external genitalia in males in animal studies[289]
Lithium	Ebstein's anomaly and other cardiovascular abnormalities including atrial flutter, bradycardia, and cardiomegaly[290-295]
Methimazole	Choanal and esophageal atresia and aplasia cutitis, associated with 1st trimester use[296]
Methotrexate	Exposure during first 6–8 weeks postconception: associated with IUGR; hypoplastic supraorbital ridges; small, low-set ears; micrognathia; limb deformities; and mental retardation Exposure during 2nd and 3rd trimesters: associated with fetal toxicity and increased mortality[297-303]
NSAIDs	Exposure during time of conception has been associated with blocking blastocyst implantation in animals Exposure after 30 weeks gestation associated with an increased risk of premature closure of the fetal ductus arteriosus, persistent pulmonary hypertension in the newborn, and oligohydramnios[304-308]
Progestins/testosterones	Exposure prior to 10th–11th week of gestation associated with masculinization of female genitalia, clitoral hypertrophy, fused or partial fused labia, possible absent vagina[309]
Retinoids/vitamin A >18,000 units per day	Translocation of the forebrain and posteriorization of the hindbrain, disruption in CNS development, microtia, low-set ears, small mouth, facial dysmorphism[126,310-315]
Tetracyclines	Discoloration of teeth and bones in children when used after 16 weeks of gestation, maternal liver toxicity[316-323]
Tobacco	IUGR, placenta previa, abruption placentae, decreased maternal thyroid function, premature rupture of membranes, low birth weight, perinatal mortality, ectopic pregnancy Children born to mothers who smoke during pregnancy at increased risk for asthma, infantile colic, and childhood obesity[324-330]
Warfarin	Exposure during the 1st trimester (critical period being weeks 6–9 gestation) often results in fetal warfarin syndrome, which consists of nasal hypoplasia, neonatal respiratory distress, low birth weight, eye defects including blindness, optic atrophy, and microphthalmia, hypoplasia of the extremities, developmental retardation, seizures, scoliosis, deafness, congenital heart disease, and death[331-334]

[a] Many of the major drug-induced congenital anomalies are discussed in the text. This table lists additional known teratogenic effects.

MANAGEMENT OF TERATOGENICITY

Due to the unpredictable nature and unknown etiologies of birth defects, it will likely be a long time before these can be avoided completely. Whenever possible, a comprehensive team should manage neonates and infants with congenital anomalies, and support should extend beyond the pediatric age. There is growing concern regarding the quality of life available to those with congenital anomalies, especially when the birth defect is visible to others. Visible birth defects can cause stereotyping, bullying, lack of self-esteem, and psychosocial issues, especially among school-aged children where physical appearance and "fitting in" are extremely important. Although some individuals are able to adjust to their differences, others face many of these issues well into adulthood.

A team of supportive healthcare providers needs to be established and available throughout the individual's life. At the time a structural defect is identified during pregnancy, the team will likely include obstetricians, neonatologists, geneticists, pediatricians, pharmacists, and pediatric surgeons to deal with the maternal and fetal complexities. Nonstructural defects will require a team of healthcare providers as well. The team should provide education to the prospective parents regarding fetal outcomes; possible interventions; appropriate setting, time, and route of delivery; and expected postnatal outcomes.[267] Some information may not be known until delivery, but support and care for the patient and family should be a primary concern. More than 50% of parents feel that counseling from a religious person should be available especially when critical decisions regarding possible termination of pregnancy are required.[268] Psychological care for the patient and caregivers should also be considered to help individuals adjust to life with their disability. This is especially important in patients with a visible defect. Open communications between team members and the family involved are key to continued success in promoting improved quality of life and managing the impact of the anomaly.

INFORMATION FOR PATIENTS

Providing information to patients regarding risks associated with medication use during pregnancy requires preparation and strong communication skills. Patients and their family members often have a lot of questions regarding the associated risks of drug exposure and rely heavily on information they find on the Internet, television, or from acquaintances.

Healthcare providers need to be prepared to answer questions regarding the drug the patient is taking, how the drug can impact pregnancy and the developing fetus, and the impact of not treating or controlling the underlying condition the drug was prescribed to treat. Additionally, information regarding confounding risk factors (e.g., maternal cigarette smoking, alcohol use, and illicit drug use) should be provided and discussed.

Patients need to understand there is a balance between risks and benefits when determining whether to take certain drugs during pregnancy. For example, phenytoin is known to increase the risk of orofacial cleft formation in infants whose mothers take the drug throughout pregnancy. However, untreated seizure disorders during pregnancy are linked to decreased fetal oxygen delivery and can increase the risks for stillbirths, miscarriages, and serious developmental delays. In this scenario, the benefits of phenytoin therapy likely outweigh the risks of orofacial cleft development. These risks and benefits must be communicated clearly to patients so they are able to make informed decisions and take an active role in their health and pregnancy management. The following databases and references include information regarding teratology:

- Reprotox.org
- Clinical Teratology Web (TERIS) is available at depts.washington.edu/terisdb/terisweb/index.html.
- Briggs GG, Freeman RK, Towers CV, Forinash AB. *Drugs in Pregnancy and Lactation: A Reference Guide to Fetal and Neonatal Risk.* 11th ed. Philadelphia, PA: Wolters Kluwer Health, 2015.
- The Organization of Teratology Information Specialists (OTIS) is available at http://mothertobaby.org/benefits-otis/.

Clinicians and patients should be encouraged to participate in pregnancy registries that are open for enrollment to increase the pool of information available.

Liraglutide, 879*t*, 884, 909*t*, 915

Lisdexamfetamine, 167*t*

Lisinopril

- alopecia and, 167*t*
- color changes of oral mucosa and teeth and, 1254*t*
- glucose/insulin dysregulation and, 688
- hypotension and, 632*t*, 638*t*
- myocardial ischemia/acute coronary syndromes and, 472*t*
- oral lichenoid reactions and, 1271*t*
- ototoxicity and, 1236*t*
- pancreatitis and, 878*t*, 879, 880, 886*t*
- photosensitivity and, 146*t*
- SIADH and, 983*t*
- systemic lupus erythematosus and, 125*t*
- taste disorders and, 1260–1261*t*

Lithium

- acidosis and, 1003*t*
- acute kidney injury and, 943*t*, 945*t*, 959
- akathisia and, 255–256*t*, 258*t*
- alopecia and, 173*t*, 175, 178, 183
- Brugada syndrome and, 547*t*
- chronic kidney disease and, 965, 966*t*, 968–970, 970*t*, 972–976, 972*t*, 974*t*
- cognitive disorders and, 358*t*, 365, 367–369
- cutaneous diseases and, 102–103*t*, 108, 109

  delirium and, 327*t*
  depression and, 391
  diabetes insipidus and, 991–993, 991*t*
  gingival hyperplasia and, 1263*t*
  monomorphic ventricular tachycardia and, 524*t*
  myocardial ischemia/acute coronary syndromes and, 473*t*
  nausea/vomiting and, 909*t*
  neuroleptic malignant syndrome and, 1195, 1195*t*, 1199, 1200
  oral lichenoid reactions and, 1270, 1271*t*
  ototoxicity and, 1236*t*
  peripheral neuropathy and, 281*t*
  serotonin syndrome and, 1203–1204*t*
  sexual dysfunction and, 758–759*t*, 761*t*
  side effects of, 254
  systemic lupus erythematosus and, 125*t*, 133
  tardive dyskinesia and, 262
  taste disorders and, 1260–1261*t*
  teratogenicity of, 1321–1322, 1334*t*
  thromboembolic diseases and, 1066*t*, 1070*t*
  thyroid diseases and, 699–700*t*, 702*t*, 704, 707–709, 713–714, 717
  visual disturbances and, 304*t*
  weight gain and, 1167–1169*t*, 1171–1172, 1173*t*
Liver diseases. *See* Hepatic and cholestatic diseases
LLLT (low-level laser therapy), 189*t*, 192
LMWH. *See* Low-molecular-weight heparin
Lobaplatin, 170*t*
Local anesthetics, 530, 1262, 1314
Lomefloxacin, 146*t*, 280*t*
Lomitapide, 7*t*, 849*t*
Lomustine, 384, 432*t*, 908*t*, 916*t*, 966*t*, 970*t*
Loop diuretics
  acute kidney injury and, 943–944*t*, 947, 953, 954
  alkalosis and, 1013–1014*t*
  gout/hyperuricemia and, 1138
  graded challenge procedure for, 95
  heart failure and, 505, 511
  hepatic/cholestatic diseases and, 847*t*
  ototoxicity and, 1239, 1241
  pancreatitis and, 883
  sexual dysfunction and, 759*t*, 764*t*
  SIADH and, 989*t*
  in sulfa drug class, 92
Loperamide, 39, 533*t*, 827*t*, 828
Lopinavir, 984*t*, 1051*t*
Loratadine, 146*t*, 539*t*, 853*t*, 1013–1014*t*

Lorazepam
- anxiety and, 407, 410
- cognitive disorders and, 369
- delirium and, 327*t*, 329*t*, 337
- hypothermia and, 1218
- nausea/vomiting and, 929, 929*t*
- neuroleptic malignant syndrome and, 1195*t*, 1200*t*
- oral lichenoid reactions and, 1271*t*
- ototoxicity and, 1236*t*
- seizures and, 226
- serotonin syndrome and, 1208, 1208*t*
- SIADH and, 984*t*
- visual disturbances and, 304*t*

Lorcainide, 502*t*, 507, 510*t*

Lorcaserin, 664

Losartan
- acute kidney injury and, 942
- asthma/bronchospasm and, 452*t*, 454
- gout/hyperuricemia and, 1138
- hypotension and, 632*t*, 638*t*
- pancreatitis and, 878*t*
- photosensitivity and, 146*t*
- taste disorders and, 1260*t*

Lovage, 304*t*

Lovastatin
- alopecia and, 171*t*
- ototoxicity and, 1236*t*
- pancreatitis and, 878*t*, 886*t*
- photosensitivity and, 146*t*
- sleep disorders and, 348*t*
- systemic lupus erythematosus and, 124*t*
- visual disturbances and, 304*t*

Low birth weight, 1311, 1316–1318

Low blood pressure. *See* Hypotension

Low-level laser therapy (LLLT), 189*t*, 192

Low-molecular-weight heparin (LMWH)
- alopecia and, 166, 178
- bleeding disorders and, 1026*t*, 1028, 1029*t*, 1032, 1036
- intracerebral hemorrhage and, 238*t*, 239, 240*t*, 242*t*, 245
- myocardial ischemia/acute coronary syndromes and, 486
- osteoporosis/osteomalacia and, 1121*t*, 1124*t*
- ovarian hyperstimulation and, 789
- thrombocytopenia and, 1052*t*, 1055–1058, 1056–1057*t*
- thromboembolic diseases and, 1064*t*, 1067, 1075, 1076

Loxapine, 326*t*, 547*t*, 582*t*, 635*t*, 639*t*, 852*t*, 1195*t*

LSD (lysergic acid diethylamide), 415, 418, 473*t*, 1188*t*
L-tryptophan, 1203–1204*t*

- patient education on, 1160
- prevention of, 1157–1158, 1158*t*
- risk factors for, 1155–1157, 1156*t*

Myositis, 1149, 1151, 1157

Nabilone, 929*t*

Nab-paclitaxel, 908*t*

Nabumetone
- acute kidney injury and, 944
- alopecia and, 172*t*
- heart failure and, 510*t*
- ototoxicity and, 1236*t*
- photosensitivity and, 146*t*, 150
- upper gastrointestinal ulceration and, 817

N-acetylcysteine (NAC)
- acute kidney injury and, 954
- asthma/bronchospasm and, 452*t*, 455, 455*t*
- heart failure and, 515
- hepatic/cholestatic diseases and, 866
- hypersensitivity reactions to, 77*t*
- ototoxicity and, 1242*t*
- serum sickness-like reactions and, 1193*t*

N-acetyl-*p*-benzoquinone imine (NAPQI), 33, 39, 856, 864, 970

N-acetylprocainamide, 134

Nadolol, 168*t*, 461, 577*t*, 632*t*, 638*t*

Nadroparin, 167*t*

Nafarelin, 700*t*

Nafcillin, 125*t*, 1188*t*

Nalbuphine, 906*t*

Nalidixic acid, 147*t*, 305*t*, 1002*t*, 1051*t*

Nalmefene, 840, 840*t*

Naloxegol, 840, 840*t*

Naloxone
- for constipation, 840–841, 840*t*
- hepatic/cholestatic diseases and, 869
- nausea/vomiting and, 927*t*
- psychosis and, 424*t*
- restrictive drug distribution system for, 7*t*
- seizures and, 218*t*

Naltrexone, 174*t*, 180*t*, 349*t*

Nandrolone, 102*t*, 167*t*, 176, 195*t*, 402, 1065*t*, 1069*t*

NANSAIDs (nonaspirin nonsteroidal anti-inflammatory drugs), 239, 816

Naphazoline, 1051*t*

NAPQI. *See* *N*-acetyl-*p*-benzoquinone imine

Naproxen

- alopecia and, 172*t*
- bleeding disorders and, 1033
- comorbidity and, 34
- drug fever and, 1188*t*
- gout/hyperuricemia and, 1145
- heart failure and, 510*t*
- hepatic/cholestatic diseases and, 846*t*
- myocardial ischemia/acute coronary syndromes and, 475, 479
- oral erythema multiforme and, 1267*t*
- oral lichenoid reactions and, 1271*t*
- ototoxicity and, 1236*t*
- pancreatitis and, 881
- photosensitivity and, 147*t*, 150
- sexual dysfunction and, 760*t*, 783*t*, 786*t*

    genetic variability and, 16*t*
    glucose/insulin dysregulation and, 682*t*, 685*t*
    hemolytic anemia and, 1101*t*, 1105*t*
    hepatic/cholestatic diseases and, 847*t*
    hypotension and, 634*t*
    monomorphic ventricular tachycardia and, 529

- neutropenia/agranulocytosis and, 1090–1091*t*, 1091
- oral lichenoid reactions and, 1272*t*
- ototoxicity and, 1237*t*
- photosensitivity and, 147*t*
- psychosis and, 417*t*
- sinus bradycardia/atrioventricular block and, 577, 578*t*
- systemic lupus erythematosus and, 124*t*, 127, 128*t*, 130
- thrombocytopenia and, 1051–1052*t*, 1052
- torsades de pointes and, 532*t*, 538, 539–540*t*
- upper gastrointestinal ulceration and, 809, 810*t*, 811, 813

Quinine
- allergic reactions to, 75*t*
- cutaneous diseases and, 102*t*
- drug fever and, 1188*t*
- glucose/insulin dysregulation and, 682*t*, 685*t*
- hemolytic anemia and, 1101*t*, 1105*t*, 1106
- neutropenia/agranulocytosis and, 1090–1091*t*
- oral erythema multiforme and, 1267*t*
- ototoxicity and, 1237*t*, 1239, 1239*t*
- photosensitivity and, 147*t*
- thrombocytopenia and, 1051–1052*t*, 1052, 1054, 1056
- torsades de pointes and, 534*t*, 539–540*t*

Quinolones, 101, 220, 316

Quinupristin–dalfopristin, 984*t*

Rabbit syndrome, 262, 265

Rabeprazole, 966*t*

Racial differences
- in constipation, 837
- cutaneous diseases and, 111–112
- in drug allergies and hypersensitivity reactions, 87
- intracerebral hemorrhage and, 241
- in nausea and vomiting, 917
- in polymorphisms, 15–16
- in prevalence of drug-induced diseases, 32, 38
- systemic lupus erythematosus and, 133

Radiocontrast media
- acute kidney injury and, 943*t*, 945*t*, 950–955
- allergic and hypersensitivity reactions to, 76–77, 77*t*, 81, 87, 97*t*, 98
- asthma/bronchospasm and, 451
- iodinated, 219*t*, 452*t*, 700*t*, 703*t*, 709, 716–717
- thyroid diseases and, 705, 709, 716–717

Raloxifene
- depression and, 386
- endometrial cancer and, 1302
- osteoporosis/osteomalacia and, 1129*t*, 1130

- thromboembolic diseases and, 1064*t*, 1068*t*, 1074, 1075*t*
- thyroid diseases and, 703*t*

Raltegravir, 103*t*, 401*t*, 403, 1127, 1267*t*

Ramelteon, 335, 337, 353

Ramipril
- acute kidney injury and, 942
- alopecia and, 167*t*
- color changes of oral mucosa and teeth and, 1254*t*
- hypotension and, 632*t*, 638*t*
- ototoxicity and, 1237*t*
- pancreatitis and, 878*t*, 879
- photosensitivity and, 147*t*
- SIADH and, 983*t*
- taste disorders and, 1260*t*

Ranibizumab, 1003*t*, 1065*t*, 1069*t*

Ranitidine
- cognitive disorders and, 366
- delirium and, 328*t*
- drug fever and, 1188*t*
- hemolytic anemia and, 1105*t*
- neutropenia/agranulocytosis and, 1090*t*

    orofacial clefts and, 1318–1319*f*, 1318–1321, 1335
    patient education on, 1335
    placental transfer mechanisms and, 1313–1314
    prevention of, 1333–1334
    teratogenicity of, 1315–1316
    in Type D reactions, 60
Terazosin, 308*t*, 632*t*, 639*t*, 1237*t*
Terbinafine
    color changes of oral mucosa and teeth and, 1254*t*
    cutaneous diseases and, 103*t*

- hepatic/cholestatic diseases and, 847*t*
- myopathy and, 1150*t*
- photosensitivity and, 148*t*
- systemic lupus erythematosus and, 125*t*, 132
- taste disorders and, 1258, 1260*t*, 1261
- thrombocytopenia and, 1051*t*

Terbutaline
- atrial tachycardia and, 588–589*t*, 589
- glucose/insulin dysregulation and, 681*t*, 684*t*
- hepatic/cholestatic diseases and, 853*t*
- monomorphic ventricular tachycardia and, 524–525*t*, 529
- myocardial ischemia/acute coronary syndromes and, 473*t*

Terconazole, 790*t*, 792

Terfenadine, 473*t*, 538, 539, 540*t*, 541, 853*t*

Teriflunomide, 172*t*

Teriparatide, 1129*t*, 1130, 1136*t*, 1140, 1150*t*

Terlipressin, 533*t*, 872

Testolactone, 167*t*, 195*t*

Testosterone
- alopecia and, 167*t*, 176, 184
- anxiety and, 402–403
- cutaneous diseases and, 102*t*
- growth hormone deficiency and, 751
- hirsutism and, 194, 195*t*, 198, 201
- hypertension and, 618*t*, 620*t*
- myocardial ischemia/acute coronary syndromes and, 473*t*, 476
- sexual dysfunction and, 763, 766, 767, 769, 798
- teratogenicity of, 1334*t*
- torsades de pointes and, 538
- visual disturbances and, 308*t*

Testosterone undecanoate, 762*t*, 765*t*

Tetrabenazine
- depression and, 376*t*, 380, 385, 385*t*
- dystonia and, 270
- parkinsonism and, 271*t*, 273*t*
- restrictive drug distribution system for, 7*t*
- tardive dyskinesia and, 264

Tetracaine, 571*t*, 1238*t*

Tetrachloroethylene, 850*t*

Tetracyclic antidepressants, 218*t*, 759–760*t*, 1170

Tetracyclines
- acidosis and, 1002*t*, 1003*t*
- allergic reactions to, 95
- color changes of oral mucosa and teeth and, 8, 1253, 1254–1255*t*, 1255–1258
- cutaneous diseases and, 101, 102–103*t*

- diarrhea and, 823*t*
- drug fever and, 1189*t*
- hepatic/cholestatic diseases and, 847*t*, 861*t*
- myopathy and, 1150*t*
- oral erythema multiforme and, 1268*t*
- oral lichenoid reactions and, 1272*t*
- ototoxicity and, 1238*t*
- pancreatitis and, 878*t*, 882, 885, 886*t*
- photosensitivity and, 143, 148*t*, 150, 150*t*, 154
- systemic lupus erythematosus and, 125*t*
- taste disorders and, 1260–1261*t*
- teratogenicity of, 1334*t*
- upper gastrointestinal ulceration and, 809, 810–811*t*, 811, 816*t*
- visual disturbances and, 308*t*

Tetrahydro-2-furanone, 1215

Tetrahydrocannabinol, 33, 744*t*

Tetramethrin, 453*t*

Teucrium polium, 851*t*

TGF (tumor growth factor), 1293

Thalidomide
- constipation and, 836*t*
- glucose/insulin dysregulation and, 681*t*, 684*t*
- hepatic/cholestatic diseases and, 848*t*
- infertility and, 783*t*, 786*t*
- interstitial lung disease/pulmonary fibrosis and, 439, 440
- leukemia and, 1286–1287
- oral lichenoid reactions and, 1272*t*
- ototoxicity and, 1238*t*
- peripheral neuropathy and, 280*t*, 282*t*, 284
- restrictive drug distribution system for, 6, 7*t*
- sinus bradycardia/atrioventricular block and, 571*t*
- teratogenicity of, 22, 23, 1312, 1321–1322, 1324
- thromboembolic diseases and, 1065*t*, 1067, 1069*t*, 1075*t*
- thyroid diseases and, 699*t*, 702*t*
- vaginal bleeding disorders and, 782*t*, 785*t*
- withdrawal from market, 5

Thallium, 171*t*, 177, 1254*t*

Theophylline
- acidosis and, 1002*t*
- acute kidney injury and, 953
- alkalosis and, 1013–1014*t*, 1017
- anxiety and, 401*t*, 404, 405*t*
- asthma/bronchospasm and, 463
- atrial fibrillation/atrial flutter and, 582–583*t*, 584, 587–588
- atrial tachycardia and, 588, 588–590*t*, 590, 591

- AV node re-entrant tachycardia and, 592–594*t*, 594
- cognitive disorders and, 365
- delirium and, 326*t*
- diarrhea and, 823*t*
- drug fever and, 1189*t*
- drug-induced hospitalizations from, 26
- drug interactions with, 39*t*
- food interactions with, 40
- monomorphic ventricular tachycardia and, 524–525*t*, 529, 530
- myocardial ischemia/acute coronary syndromes and, 473*t*
- nausea/vomiting and, 909*t*
- oral erythema multiforme and, 1268*t*
- seizures and, 218*t*, 219, 222, 222*t*, 224, 226
- SIADH and, 984*t*
- sleep disorders and, 349*t*

Thiabendazole, 847*t*, 1238*t*, 1268*t*

Thiacetazone, 1138

Thiamazole, 124*t*, 1088

Thiamine (vitamin B_1), 265, 285, 362, 1009

Thiazide diuretics
- acute kidney injury and, 943*t*
- alkalosis and, 1013–1014*t*
- cutaneous diseases and, 101
- depression and, 378
- glucose/insulin dysregulation and, 680*t*, 684*t*
- gout/hyperuricemia and, 1138
- hepatic/cholestatic diseases and, 847*t*
- pancreatitis and, 878*t*, 886–887
- sexual dysfunction and, 759–760*t*, 761, 764*t*, 772
- SIADH and, 984*t*, 987
- in sulfa drug class, 92

Thiazolidinediones, 476, 849*t*, 1121*t*, 1124*t*, 1172

Thienopyridines, 811, 815

Thiethylperazine, 1238*t*

Thioamides, 703*t*, 716, 885, 888

Thioguanine, 848*t*, 880

Thiopental, 73*t*, 871, 907*t*

Thiopropazate, 265

Thioridazine
- delirium and, 326*t*, 329*t*
- drug fever and, 1189*t*
- hepatic/cholestatic diseases and, 852*t*
- hypotension and, 635*t*, 639*t*
- hypothermia and, 1216*t*
- monomorphic ventricular tachycardia and, 524*t*

- neuroleptic malignant syndrome and, 1195*t*
- photosensitivity and, 148*t*
- sexual dysfunction and, 798
- SIADH and, 983*t*
- sinus bradycardia/atrioventricular block and, 573*t*
- thromboembolic diseases and, 1066*t*, 1070*t*
- thyroid diseases and, 703*t*
- torsades de pointes and, 533*t*, 540*t*
- visual disturbances and, 308*t*
- weight gain and, 1167*t*, 1169*t*, 1171

Thiotepa, 170*t*, 177, 358*t*, 848*t*, 983*t*

Thiothixene
- delirium and, 338
- hypotension and, 635*t*, 639*t*
- neuroleptic malignant syndrome and, 1195*t*
- seizures and, 221
- SIADH and, 983*t*
- thrombocytopenia and, 1051*t*
- weight gain and, 1167*t*

Thioxanthenes, 743*t*

Third-degree AV block, 569, 572, 575, 578

Thrombin inhibitors, 239, 487*t*, 1026*t*, 1029*t*, 1034, 1057–1058, 1076

Thrombocytopenia, 1049–1059
- causative agents of, 1049–1050, 1050–1051*t*
- clinical presentation of, 83–84, 1054–1056, 1054*t*
- differential diagnosis of, 1055, 1055*t*
- epidemiology of, 1050, 1052
- management of, 1057–1059
- mechanisms of, 1052–1054, 1052*t*
- morbidity and mortality for, 1056
- patient education for, 1059
- prevention of, 1056–1057, 1057*t*
- risk factors for, 1056, 1056*t*

Thromboembolic diseases, 1063–1078
- causative agents of, 1063, 1064–1066*t*
- clinical presentation of, 1071–1073, 1071*t*
- differential diagnosis of, 1072, 1072*t*
- epidemiology of, 1063, 1066
- management of, 237, 1076–1077
- mechanisms of, 1067–1071, 1068–1071*t*
- morbidity and mortality for, 1074
- patient education on, 1077–1078
- prevention of, 1074–1075, 1075*t*
- risk factors for, 1073–1074, 1073*t*

Thrombolytic agents

- bleeding disorders and, 1025, 1026*t*, 1029*t*, 1030, 1033–1034, 1039
- hepatic/cholestatic diseases and, 868
- intracerebral hemorrhage and, 238*t*, 240*t*, 243, 244*t*, 245
- myocardial ischemia/acute coronary syndromes and, 486, 487*t*, 488

Thrombotic thrombocytopenia purpura–hemolytic uremic syndrome (TTP-HUS), 1054, 1056

Thyroid diseases, 697–717. *See also* Hyperthyroidism; Hypothyroidism
- causative agents of, 697–701, 698–700*t*, 704
- clinical presentation of, 711–713, 711*t*
- comorbidity with drug-induced diseases, 34
- differential diagnosis of, 711, 712, 712*t*
- epidemiology of, 704
- management of, 715–717, 715*t*
- mechanisms of, 697, 698*f*, 701–703*t*, 704–710, 706–707*t*

DRUG-INDUCED DISEASES: PREVENTION, DETECTION, AND MANAGEMENT, THIRD EDITION

FROM THE FOREWORD:

"Drug-Induced Diseases: Prevention, Detection, and Management is an extraordinary work that continues to be the standard for understanding and preventing drug-induced diseases. It can be a practitioner's most useful tool."

John A. Gans, PharmD
Professor and Dean (Emeritus), Philadelphia College of Pharmacy, and CEO (Emeritus), American Pharmacists Association

Drug-induced diseases are unintended effects of drugs that result in mortality or morbidity with symptoms sufficient to prompt a patient to seek medical attention and/or require hospitalization. *Drug-Induced Diseases: Prevention, Detection, and Management* provides a detailed overview of diseases that result from drug therapy, arming healthcare professionals with critical knowledge to protect the health and welfare of their patients.

Now in its third edition, this important reference helps healthcare practitioners, residents, and students by expanding the understanding of disease state causes and effects, encouraging critical thinking and raising awareness that many diseases can be caused or exacerbated by a medication the patient is taking.

The third edition has been revised and expanded:

- **58 peer-reviewed chapters authored by 99 contributors**
- **Detailed, comprehensive tables**
- **New chapters including Bleeding Disorders, Teratogenicity, and Oral Manifestations of Systemically Administered Drugs**
- **Comprehensive coverage of scores of drug-induced diseases**
- **Information pertaining to the contribution of genetic polymorphisms to specific drug-induced diseases**
- **"Levels of evidence" classification for identifying the strength of evidence that links a listed drug to a specific drug-induced disease**
- **And much more**

Edited by James E. Tisdale and Douglas A. Miller, with contributions from distinguished experts, *Drug-Induced Diseases: Prevention, Detection, and Management* is organized for easy use by pharmacists, physicians, nurses, and other healthcare professionals, as well as by students and trainees.
